STATIC AND ESR SUSCEPTIBILITIES OF THE AMBIENT PRESSURE SUPERCONDUCTORS
β- AND α-(BEDT-TTF)$_2$I$_3$ AND (BEDT-TTF)$_2$Cu(SCN)$_2$

(Received July 10, 1988 by M. Cardona)

Whereas the static spin-susceptibility $\chi_s(T)$ of β- and α-(BEDT-TTF)$_2$I$_3$ at 5.7 tesla increases in a slow monotonic manner with temperature, $\chi_s(T)$ for the organic superconductor (BEDT-TTF)$_2$Cu(SCN)$_2$ displays a markedly structured temperature dependence. This gives evidence for two or more phase transitions in the metallic phase at temperatures near 100 K and 50 K, in addition to the onset of superconductivity at 5.7 tesla below ~8 K. Good agreement is found between the absolute magnitudes of static and ESR susceptibility results, thus confirming that orbital susceptibility contributions are of negligible importance here. Cooling in low magnetic fields reveals that superconductivity in (BEDT-TTF)$_2$Cu(SCN)$_2$ sets in at a temperature near 8.5 K, with a 7.6% Meissner effect in 14 G field.

1. Introduction

The discovery$^1$ in 1981 of superconductivity near 1 K in (TMTSF)$_2$PF$_6$ under pressure has been followed by the synthesis of approximately fifty further organic superconductors, a number of which are superconducting at ambient pressure. The highest values of the superconducting transition temperature $T_c$ have involved radical salts obtained from the organic donor BEDT-TTF (bisethylenedithiolotetrathiafulvalene). Subjecting the 1 K - superconductor β-(BEDT-TTF)$_2$I$_3$ to a particular pressure/temperature cycle$^2$ results in a compound with a slightly altered structure which is superconducting at 8 K; unfortunately, this altered structure is only stable for temperatures below 125 K. The discovery$^3$, and confirmation of ambient-pressure superconductivity at 8 K in α-(BEDT-TTF)$_2$I$_3$ is thus of considerable importance because the α-phase remains stable for all temperatures below 350 K. The α-phase is obtained directly from nonsuperconducting α-(BEDT-TTF)$_2$I$_3$ by annealing at 70°C for approximately four days. The crystal structures of the β- and α-phases are quite similar, although the precise relative atomic positions in the α-phase are not yet established. The close similarity of the β- and α-structures is also supported by $^{13}$C-NMR, ESR-linewidth, and Raman measurements.$^4$

The existence of a new ambient pressure BEDT-TTF superconductor with the counter anion Cu(SCN)$_2$ has recently been reported by Urayama et al.$^5$ and confirmed by Gärtner et al.$^6$ The resistive midpoint of the superconducting transition occurs at approximately 10.4 K, the highest $T_c$-value reported to date for an organic superconductor. Although x-ray diffraction results$^7$ reveal that no change in phase occurs in this compound between 300 K and 104 K, recent thermopower studies$^8$ point to possible phase transitions at temperatures near 90 K and 50 K. Whereas the electrical resistivity passes through a clear maximum at ~90 K$^9,10$ and the static magnetic susceptibility data $\chi_s$ appear to fall off somewhat below 90 K,$^9$ the ESR susceptibility data are not sufficiently accurate to resolve any structure in $\chi_s(T)$.$^9$ Some questions still remain unclarified concerning the precise atomic coordinates in this compound at low temperatures.

Measurements of the Pauli spin-susceptibility $\chi_s$ provide information on the density of electron states at the Fermi energy $N(E_F)$ as well as on the importance of electron-electron interactions. Whereas the temperature and pressure dependences of the spin-susceptibility of the Bechgaard salts$^9$ (eg. (TMTSF)$_2$PF$_6$, TTF-TCNQ,$^{10,11}$ and other organic metals$^{11}$) are often highly anomalous, $\chi_s$ for α- or β-(BEDT-TTF)$_2$I$_3$ is found to change relatively little with temperature or pressure.$^5,12$ In the present paper we present precision measurements of $\chi_s(T)$ for α-(BEDT-TTF)$_2$I$_3$ and (BEDT-TTF)$_2$Cu(SCN)$_2$. The magnetic susceptibility was measured using both static Faraday and standard ESR techniques. Experimental preparation and measurement techniques have been given in previous papers.$^4,6,12$

2. Results on α-(BEDT-TTF)$_2$I$_3$

The static spin-susceptibility $\chi_s(T)$ at 5.7 tesla of a 96 mg sample of randomly oriented crystals of α-(BEDT-TTF)$_2$I$_3$, is plotted in Fig. 1 as a function of temperature. $\chi_s(T)$ for the β-phase of the same compound is also shown. Since in the virgin α-phase $\chi_s(T)$ drops sharply due to the metal-insulator transition as
temperature \( \chi_a(T) \) falls for both phases at a slow monotonic rate which increases distinctly for temperatures below \( \sim 100 \) K for the \( \beta \)-phase and \( \sim 150 \) K for the \( \alpha_\beta \)-phase. At least part of this temperature dependence can be attributed to thermal contraction effects, as emphasized by Klotz et al.\(^\text{10} \) for the \( \beta \)-phase. The more severe decrease in \( \chi_a(T) \) below 100 K for the \( \beta \)-phase may be due to the distortion of the linear \( \text{I}_3 \)-anion chains below 125 K in this \( \text{T}_{\text{c}} = 1 \) K superconductor. At room temperature, \( \chi_a \approx + (4.6 \pm 0.1) \times 10^{-4} \), and \(+ (4.5 \pm 0.07) \times 10^{-4} \) emu/mole for the \( \alpha_\gamma \), \( \beta \)-, and \( \alpha \)-phases, respectively (since \( \chi_{\text{core}} \) is the same for all three phases, the above error limits do not include the uncertainty in \( \chi_{\text{core}} \) ); using the simple formula \( \chi_a = 2 \mu_0 N(E_f) \), we derive, respectively, the values \( N(E_f) = 10.5, 7.1, \) and 6.9 states/(eV-spin-f.u.).

The relative temperature dependence of the spin-susceptibility \( \chi_a \) for crystals of \( \alpha_\gamma-(\text{BEDT-TTF})_2\text{I}_3 \) was previously investigated by standard ESR methods in the temperature range from 5 - 300 K.\(^{4} \) We have recently determined the absolute value of \( \chi_a \) for this compound in the following way: first, we measured the ESR signal of a single crystal of \( \alpha_\gamma-(\text{BEDT-TTF})_2\text{I}_3 \) and calculated \( \chi_a(\alpha) \) in the usual way from the linewidth and the intensity of the signal in arbitrary units.\(^{12} \) The same single crystal was then annealed for several days at 70°C in order to obtain the \( \alpha \)-phase.\(^{4} \) After this procedure the ESR signal of this \( \alpha_\gamma-(\text{BEDT-TTF})_2\text{I}_3 \) crystal was measured and \( \chi_a(\alpha) \) was calculated again. Fig. 2 shows the ESR signal of the conduction electrons at 300 K for both phases. For the \( \alpha \)-crystal the sensitivity of the ESR receiver was eight times higher than for the transformed \( \alpha_\gamma \)-crystal. The ratio of the two susceptibilities obtained was \( \chi_a(\alpha) / \chi_a(\alpha) = 0.686 \pm 0.02 \) at room temperature. Taking the value of \( \chi_a(\alpha) = + (4.6 \pm 0.14) \times 10^{-4} \) emu/mole from Ref. 12 we thus obtain \( \chi_a(\alpha) = + (4.6 \pm 0.14) \times 10^{-4} \) emu/mole, a value which agrees well with the above value from the present static susceptibility measurement.

3. Results for \( (\text{BEDT-TTF})_2\text{Cu(SCN)}_2 \)

In Fig. 3 the spin-susceptibility \( \chi_a(T) \) of a 74 mg sample of the new organic superconductor \( (\text{BEDT-TTF})_2\text{Cu(SCN)}_2 \) is compared to that of the \( \alpha_\gamma \)-phase (the value of the core diamagnetism for this compound

![Fig. 1](image-url) Static spin-susceptibility of \( \beta \)- and \( \alpha \)-
(\text{BEDT-TTF})\text{I}_3 as a function of temperature in a
magnetic field of 5.7 tesla. Data for \( \beta \)-phase are taken
from Ref. 12. Vertical lines give error in \( \chi_s \) for the
\( \alpha \)-phase assuming the temperature independent value
\( \chi_{\text{core}} = -5.2 \times 10^{-4} \) emu/mole. Similar error bars apply
for the \( \beta \)-phase.

![Fig. 2](image-url) ESR signal of a single crystal of \( \alpha_\gamma-(\text{BEDT-TTF})_2\text{I}_3 \) before and after the heat treatment which transforms it into the \( \alpha \)-phase. The ESR curve for the \( \alpha \)-phase has been magnified eightfold; it is seen to be broader than for the \( \alpha_\gamma \)-phase which has a width similar to that for the \( \beta \)-phase (Ref. 4.12).
is due to a decrease in carrier charge density as a gap opens up; such a carrier charge decrease would lead to a decrease in $\chi_s$ as found for $\alpha'-(\text{BEDT-TTF})_2I_3$. The value of the spin-susceptibility of $(\text{BEDT-TTF})_2\text{Cu}(\text{SCN})_2$ at 280 K ($\chi_s(280\text{ K}) = +(4.6 \pm 0.08)\times10^{-4}$ emu/mole) allows the estimate $N(E_F) = 7.1$ states/(eV-spin-f.u.), in good agreement with the work of Nozawa et al.\textsuperscript{13} who argue that this value appears to be strongly enhanced.

We have recently determined directly in an ESR experiment that $\chi_s(300\text{ K}) = +(4.4 \pm 0.4)\times10^{-4}$ emu/mole for $(\text{BEDT-TTF})_2\text{Cu}(\text{SCN})_2$. This value compares well with that from the above static Faraday measurements. The relatively large error in the ESR value originates from inaccuracies in weighing the tiny crystal $(530 \pm 50\mu g)$. The good agreement between the magnitude of the spin-susceptibility as derived from both static susceptibility and ESR work indicates that orbital contributions to the static susceptibility are relatively unimportant.

The low-field static susceptibility of $(\text{BEDT-TTF})_2\text{Cu}(\text{SCN})_2$ was measured upon cooling (Meissner effect), as shown in Fig. 4. No attempt was made to correct the measured data for demagnetization factor effects as the sample consisted of 74 mg of finely subdivided crystals with random orientation. From these data and the known volume per mole (908.4 cm$^3$/mole), the percentage of the full Meissner effect ($\chi = -1/4\pi$ emu/cm$^3$) at low temperatures (2 K) is estimated to be 7.6% at 14 G, 3.9% at 40 G, 2.6% at 60 G, 2.0% at 80 G, 1.5% at 106 G, and 0.00074% at 5.7 tesla (from Fig. 3). In an ac susceptibility measurement at 0.3 G an effect of at least 70% was observed.\textsuperscript{6} At low fields the onset of superconductivity is seen to occur at temperatures near 8.5 K. Urayama et al.\textsuperscript{5} find a similar onset temperature with ~5% Meissner signal for 100 G applied field. In contrast to the results of Nozawa et al.,\textsuperscript{13} we observe no increase in the low-field susceptibility curves.
as the sample is cooled below 6 K, underscoring the relative freedom of our samples from paramagnetic impurities. The fact that a clear transition toward diamagnetism is still observed near 8 K for an applied field of 5.7 tesla (Fig. 3) speaks for an unusually high value of $H_{c2}$. Oshima et al.\textsuperscript{14} have estimated that for $H \parallel c$, $H_{c2}(7 \text{~K}) \approx 10$ tesla and $\partial H_{c2}/\partial T \approx -4$ tesla/K.
