Regulation of the mannitol utilization genes in *Bacillus subtilis*
I hereby assure that I performed the present study independently without further help or other materials than stated.

Stuttgart, 15th June 2012
Acknowledgements

- I would like to thank my doctoral advisor, Prof. Dr. Ralf Mattes, for his support during the past four years, and his critical suggestions for the correction of this dissertation. Additionally, I would like to thank Prof. Dr. Dieter Jendrossek, co-examiner of this doctoral thesis.
- I also appreciate Prof. Dr. Andreas Stolz and Prof. Dr. Jens Kurreck for their helpful recommendation letters during the study.
- I would like to express my deepest gratitude to my supervisor, Dr. Josef Altenbuchner, whose expertise and guidance inspired me to develop new ideas during this project. His caring and trust provided an excellent chance for the accomplishment of my research. I have learned a lot from him.
- I also wish to thank Dr. Hildegard Watzlawick, whose unforgettable efforts in August 2008 made it possible for me to begin this study in Germany. I appreciate her support during this study and her suggestions for improving the biochemical trials.
- Special thanks should be given to my colleagues in the Bacillus subtilis research group, Dr. Tianqi Sun, Marian Wenzel and others.
- Special thanks to Silke Weber and Gisella Kwiatkowski for their assistance in this research.
- I would like to thank my colleagues and friends Dr. Jana Hoffmann and Dr. Stefan Söllner for their support, help, and guidance during this study.
- Special thanks to my colleagues in laboratory 3 of Institut für Industrielle Genetik, Marina Boose and Lei Wang for providing a friendly atmosphere during this study.
- Last but not the least, I would like to thank all other colleagues whose names are not mentioned here, but their friendly criticism, advice and suggestions have always been constructive.

Summary

_Bacillus subtilis_ takes up mannitol by a phosphoenolpyruvate-dependent phosphotransferase system (PTS). The mannitol utilization system is encoded by the _mtlAFD_ operon consisting of _mtlA_ (encoding membrane-bound EIICB^{Mtl}), _mtlF_ (encoding phosphocarrier EIIA^{Mtl}), and _mtlD_ (encoding mannitol 1-phosphate dehydrogenase). This operon is activated by MtlR whose coding gene is located approx. 14.4 kb downstream of the operon. The regulation of the mannitol utilization genes in _B. subtilis_ was studied by fusion of the promoters of _mtlAFD_ (_P_{mtlA})_ and _mtlR_ (_P_{mtlR})_ to _lacZ_ as a reporter gene. Both the _P_{mtlA} and _P_{mtlR} were inducible by mannitol and glucitol, while glucose reduced their activities. The promoter strength of _P_{mtlA} was about 4.5-fold higher than that of _P_{mtlR}. Identification of the transcription start sites of _P_{mtlA} and _P_{mtlR} revealed that both of these promoters contain a σ^A-type promoter structure. The promoter -35 and -10 boxes in _P_{mtlA} were TTGTAT and TAACAT and in _P_{mtlR} TTGATT and TATATT, respectively. Catabolite responsive elements (cre) were detected in the sequences of _P_{mtlA} and _P_{mtlR} overlapping the -10 boxes. Shortening the mRNA 5’untranslated region (5’UTR) increased the _P_{mtlA} activity, whereas _P_{mtlR} activity was decreased by shortening of its mRNA 5’UTR. Alignment of the -35 upstream sequences of _P_{mtlA} and _P_{mtlR} revealed the putative MtlR binding site. This sequence comprised a similar incomplete inverted repeat in both the _P_{mtlA} and _P_{mtlR} sequences (TTGNCACAN4TGTGNCAA). This sequence was encompassed by two 11 bp distal and proximal flanking sequences. Construction of _P_{mtlA-P_{licB}} hybrid promoters and shortening of the 5’-end of _P_{mtlA} indicated the probable boundaries of putative MtlR binding site in _P_{mtlA}. Increasing the distance between the putative MtlR binding site and -35 box lowered the _P_{mtlA} maximal activity, although _P_{mtlA} remained inducible by mannitol. _P_{mtlA} became inactive by disruption of the TTGNCACAN4TGTGNCAA sequence. In contrast, manipulation of the distal and proximal flanking sequences only reduced the maximal activity of _P_{mtlA}, whereas _P_{mtlA} remained highly inducible. These flanking sequences contained AT-rich repeats similar to the consensus sequence of αCTD binding sites. It is assumed that MtlR binds to the TTGNCACAN4TGTGNCAA sequence, whereas two αCTD monomers bind to AT-rich sequences upstream and downstream of MtlR binding site. In this way, the mechanism of class I activation was proposed for _P_{mtlA} and _P_{mtlR} transcription initiation.
Regulation of $P_{mtlA}$ and $P_{mtlR}$ was investigated by deletion of $mtlAF$, $mtlF$, $mtlD$, and $mtlR$. Deletion of the $mtlAF$ genes rendered $P_{mtlA}$ and $P_{mtlR}$ constitutive showing the inhibitory effect of EIICB$^{Mtl}$ and EIIA$^{Mtl}$ (PTS transporter components) on MtlR in the absence of mannitol. The constitutive activity of $P_{mtlA}$ was increased by the deletion of $mtlF$. In contrast, the deletion of $mtlAFD$ showed a significant reduction in the $P_{mtlA}$ constitutive activity. Disruption of $mtlD$ made $B. subtilis$ sensitive to mannitol in a way that addition of mannitol or glucitol to the bacterial culture ended in cell lysis. Besides, $P_{mtlA}$ and $P_{mtlR}$ were similarly induced by glucitol and mannitol in a $mtlD::erm$ mutant. Also, deletion of $mtlR$ rendered $P_{mtlA}$ and $P_{mtlR}$ uninducible by mannitol or glucitol. In contrast, deletion of the glucitol utilization genes had no influence on the inducibility of $P_{mtlA}$ or $P_{mtlR}$ by glucitol. The $P_{mtlA}$ activity was drastically reduced in $ptsH$-H15$^A$ (HPr-H15$^A$) mutant similar to the $\Delta mtlR$ mutant. The mutation of histidine 289 in the PRDI domain of MtlR to alanine reduced the activity of $P_{mtlA}$, whereas the $P_{mtlA}$ activity in the $mtlR$-$H230A$ mutant was almost similar to wild type. In contrast, mutation of the PRDII domain of MtlR to H342D mainly relieved $P_{mtlA}$ from glucose repression. Moreover, MtlR double mutant H342D C419A which was produced in $E. coli$ was shown to be active in vitro. These results represent the positive regulation of MtlR via phosphorylation of the PRDII domain by HPr(H15$~P$). Also, dephosphorylation of the domains EII$B^{Gat}$- and EIIA$^{Mtl}$-like of MtlR by EIIA$^{Mtl}$ and EIICB$^{Mtl}$ transporter components causes activation. The $P_{mtlA}$ activity was repressed in the presence of glucose and fructose, while sucrose and mannose had no influence on the $P_{mtlA}$ activity. Therefore, catabolite repression of $P_{mtlA}$ and $P_{mtlR}$ were studied by CcpA-dependent carbon catabolite repression mutants, such as $ptsH$-S46$^A$, $\Delta crh$, $\Delta hprK$, and $\Delta ccpA$. Induction of $P_{mtlA}$ and $P_{mtlR}$ in these mutants did not result in a complete loss of catabolite repression. Therefore, the catabolite responsive elements ($cre$ sites) of $P_{mtlA}$ and $P_{mtlR}$ were investigated. Using a constitutive promoter, $P_{groE}$, it was shown that the $cre$ sites of $P_{mtlA}$ and $P_{mtlR}$ were weakly functional. In contrast, deletion of the glucose PTS transporter, encoded by $ptsG$, resulted in a complete loss of glucose repression in $P_{mtlA}$ and $P_{mtlR}$. Thus, the main glucose repression of mannitol PTS function at the posttranslational level in a HPr-mediated manner via MtlR-H342 and at transcriptional level by CcpA-dependent carbon catabolite repression.

Finally, $P_{mtlA}$ was tested for its application as a heterologous gene expression system based on a derivative of pUB110 with high copy number in the cell. Further studies showed that a
single copy of $mtrR$ controlled by its own promoter ($P_{mtrR}$-$mtrR$) on the chromosome was not enough for the activity of $P_{mtrA}$ on a high copy number vector. Thus, $P_{mtrR}$-$mtrR$ was inserted into the same vector. In this case, the induced $P_{mtrA}$ activity and its basal activity increased. Ultimately, a highly inducible expression system based on mannitol as a cheap inducer was constructed.
Zusammenfassung

wurden AT-reiche Wiederholungen identifiziert, welche Ähnlichkeit zu der Konsensus-Sequenz von αCTD aufweisen. Es wird angenommen, dass MtlR an die Sequenz TTGNACAN₄TGTGNCAA bindet und zwei αCTD Monomere an AT-reichen Sequenzen, die sich jeweils stromaufwärts bzw. stromabwärts dieser MtlR-Bindestelle befinden. Dies lässt auf einen Mechanismus der Klasse 1 schließen.

Die Regulation von \( P_{mtlA} \) und \( P_{mtlR} \) wurde mit Hilfe von \( mtlAF-\), \( mtlF-\), \( mtlD-\) und \( mtlR-\)Deletionen in \( B.\ subtilis \) untersucht. Die Deletion von \( mtlAF \) führte zu einer konstitutiven Aktivität von \( P_{mtlA} \) und \( P_{mtlR} \), wodurch der inhibitorische Effekt von EIIIC\( ^{\text{Mtl}} \) und EIIA\( ^{\text{Mtl}} \) (Untereinheiten des PTS-Transporters) auf MtlR bei Abwesenheit von Mannitol gezeigt werden konnte. Die konstitutive Aktivität von \( P_{mtlA} \) wurde durch die Deletion von \( mtlF \) noch verstärkt. Im Gegensatz dazu verursachte die Deletion von \( mtlAFD \) eine signifikante Reduktion der konstitutiven Aktivität von \( P_{mtlA} \). Die Mutation von \( mtlD \) resultierte in einer Sensitivität von \( B.\ subtilis \) gegenüber Mannitol und Glucitol. Kultivierung in Gegenwart dieser Zucker führte zu einer Lyse der Zellen. In der \( mtlD::erm \) Mutante wurden \( P_{mtlA} \) und \( P_{mtlR} \) durch Glucitol und Mannitol gleichermaßen induziert. Ferner führte die Deletion von \( mtlR \) zu einer Uninduzierbarkeit von \( P_{mtlA} \) und \( P_{mtlR} \) mit Mannitol und Glucitol, wohingegen die Deletion der Gene für die Glucitol-Verwertung keinen Einfluss auf die Induzierbarkeit von \( P_{mtlA} \) und \( P_{mtlR} \) mit Glucitol hatte. Wie auch in der \( \Delta mtlR \) Mutante war die Aktivität von \( P_{mtlA} \) in der \( ptsH-H15A \) (HPr-H15A) Mutante stark reduziert. Die Mutation des Histidin 289 in der PRDI-Domäne von MtlR zu einem Alanin reduzierte die Aktivität von \( P_{mtlA} \), während die Aktivität von \( P_{mtlA} \) in der \( mtlR-H230A \)-Mutante ähnlich wie die des Wildtyps war. Im Gegensatz dazu führte die Mutation H342D der PRDII-Domäne von MtlR zu einer verminderten Glucose-Repression von \( P_{mtlA} \). Eine MtlR Doppelmutante H342D C419A wurde in \( E.\ coli \) produziert und ihre Aktivität in einem Gelmobilityshiftassay \textit{in vitro} bestätigt. Diese Ergebnisse zeigen, dass MtlR einer, durch die Phosphorylierung der PRDII-Domäne durch HPr(H15\~P) stattfindenden, positiven Regulation unterliegt. Ferner kann eine Aktivierung von MtlR durch eine Dephosphorylierung der EIIB\( ^{\text{Gat}} \) und EIIA\( ^{\text{Mtl}} \)-ähnlichen Domänen durch die EIIA\( ^{\text{Mtl}} \) und EIIIC\( ^{\text{Mtl}} \) Transporter-Untereinheiten erreicht werden. Glucose und Fructose reprimieren die Aktivität von \( P_{mtlA} \) wohingegen Saccharose und Mannose keinen Einfluss auf die \( P_{mtlA} \)-Aktivität haben. Daher wurde die Kohlenstoff-Katabolit-Repression von \( P_{mtlA} \) und \( P_{mtlR} \) in CcpA-abhängigen Mutanten, wie
Summary

Die Anwendbarkeit des \( P_{mtlA} \) als Kontrollelement für eine homologe- oder heterologe Genexpression wurde untersucht. Hierzu wurde ein Expressionsvektor basierend auf dem pUB110 Vektor, der einer hohe Kopienzahl aufweist, konstruiert. Jedoch zeigte sich, dass für die Kontrolle des \( P_{mtlA} \) eine chromosomale Kopie von \( mtlR \) nicht ausreichend ist. Das Vorhandensein von \( P_{mtlR}-mtlR \) auf dem Vektor führte jedoch zu einer Erhöhung der Basalaktivität sowie der maximalen Aktivität. Letztendlich wurde ein gut regulierbares, auf dem günstigen Induktor Mannitol basierendes Expressionssystem konstruiert.
1. Introduction

The genus *Bacillus* was named by changing the name of Ehrenberg’s “*Vibrio subtilis*” to *Bacillus subtilis* by Ferdinand Cohn in 1872 (33, 53, 85). However, it was only from about 1920 that the genus *Bacillus* was defined to include aerobic, endospore-forming, and rod-shaped bacteria (31). This genus is one of the most diverse and commercially useful groups of the bacteria (85). Among them, *Bacillus subtilis* is an ubiquitous microorganism found in soil, water, and air (50). Development of *B. subtilis* as a bacterial model system began over 60 years ago with the pioneering mutagenesis studies (25). Later, it was found that *B. subtilis* 168, a tryptophan auxotrophic mutant, produced naturally competent cells relevant for genetic transformation (206). *B. subtilis* as a Gram-positive bacterium belongs to the Firmicutes with a low G + C content. At first, the entire genome of *B. subtilis* 168 was published in 1997 (117). A decade later, *B. subtilis* genome was resequenced and the data are readily available in GenoList database (http://genodb.pasteur.fr/cgi-bin/WebObjects/GenoList) (9). Whole genome sequencing of *B. subtilis* 168 showed that this bacterium has 4,214,810 base pairs comprising of 4,100 protein-coding frames (117). Several characteristics of *B. subtilis* including biofilm formation, cannibalism, natural competence, motility, as well as endospore formation turned *B. subtilis* into a reference model for research applications (50, 78, 138, 205).

1.1. *B. subtilis* as an industrial host

Production and secretion of homologous extracellular enzymes, such as α-amylase, alkaline protease, alkaline phosphatase, esterase, etc., at gram per liter concentrations made *B. subtilis* an important source for industrial enzymes. Due to the presence of such a huge capacity for protein secretion, *B. subtilis* was also exploited as a workhorse for production and secretion of heterologous proteins in order to facilitate the downstream processing (87, 134, 201). Heterologous enzymes, such as acid-stable α-amylase from *B. licheniformis* (3.1 g/l), as well as pharmaceutical proteins, e.g. human interleukin-3 (100 mg/l), were successfully produced and secreted into the growth medium (92, 243). The mentioned proteins are two examples of the
successfully produced enzymes, pharmaceutical proteins, and vaccine components summarized in table 1.1 (57, 188, 219, 244).

Indeed, there are some advantages in employing *B. subtilis* as an expression host for secreted proteins rather than *E. coli*, especially for production of pharmaceutical proteins. As a Gram-negative member, *E. coli* possesses lipopolysaccharide, a.k.a. endotoxin, and secretes the proteins into the periplasm both of which make the downstream processing costly and laborious (134). In contrast, *B. subtilis* has a huge capacity for secretion of the proteins into the medium. It is also a non-pathogen microorganism generally recognized as safe (GRAS). Finally, it has no significant biased codon usage. Nevertheless, there are some bottlenecks using *B. subtilis* as an expression host including: (i) plasmid instability, (ii) lack of proper expression systems, (iii) low level of protein productions due to inefficient DNA transcription, mRNA translation, protein translocation, or protein folding, and (iii) the presence of 44 known and 27 putative proteases and peptidases (Fig. 1.1) (134). The latter obstacle was highly solved by deletion of the protease encoding genes (listed in table 1.2). In fact, deletion of the *aprE* (serine alkaline protease) and *nprE* (neutral protease) resulted in reduction of the extracellular protease activity of *B. subtilis* to less than 4% of the wild type strain (110).
Fig. 1. Some of the proteases and peptidases of *B. subtilis* during the vegetative growth are depicted according to Westers *et al.* (244). The sporulation proteases and peptidases as well as the proteases involved in peptidoglycan maturation are not demonstrated.

Co-expression of the chaperones, and thio-disulfide oxidoreductases, stabilizing the 5’- and 3’-ends of the mRNA, improvement of the translational initiation by changing the Shine-Dalgarno enhanced the production of some proteins (60, 134, 198, 233, 244). Nonetheless, all of the mentioned strategies are dependent on a strong and tightly regulated gene expression system.
1.2. The choice of plasmid for cloning and gene expression in *B. subtilis*

Enhancement of gene expression based on stable plasmids and tightly regulated promoters is the first step of heterologous (or homologous) protein overproduction. *B. subtilis* 168, the common laboratory strain, does not contain any plasmid. However, several cryptic rolling circle plasmids were isolated from *B. subtilis* isolates. These cryptic plasmids are classified in six groups, represented by pTA1015, pTA1020, pTA1030, pTA1040, pTA1050, pTA1060 (149, 228). These isolated plasmids do not confer any selectable phenotypes to their host. Therefore, most cloning vectors for *B. subtilis* are based on rolling circle-type replication plasmids from other Gram-positive bacteria such as Staphylococci or Streptococci (Table 1.3) (19-21, 81, 149, 164). For instance, pUB110 is a rolling circle-type plasmid originating from *Staph. aureus*. The derivatives of pUB110 are commonly used for gene expression in *B. subtilis*. Generally, a plasmid comprises two origins of replication in the rolling circle replication: a plus origin, which is responsible for formation of ssDNA, and a minus origin, which is the initiation site for complementary strand replication. The minus origin is not necessary for the replication of the plasmid (81). Therefore, this site was accidentally deleted in many plasmids during the vector construction. Consequently, these plasmids are frequently unstable due to the formation of ssDNA or by accumulation of high molecular weight linear head to tail DNA (21). In addition to rolling circle-type plasmids, theta-type plasmids are also widely applied for the cloning of desired genes in *B. subtilis*. Among them, pAMβ1 is widely employed. Plasmid pAMβ1 originates from *Enterococcus faecalis* and replicates in an unidirectional theta-type replication (24, 32, 127). However, this plasmid has a large size (approx. 26.5 kb) and low copy number (1 – 5 copies per chromosome) (32). In addition to pAMβ1, a low-copy theta-type plasmid, called pBS72, is also used for construction of vectors in *B. subtilis*. Plasmid pBS72 was isolated from a *B. subtilis* strain (220). Due to the low copy number or low transformation frequency of the rolling circle-type and theta-type vectors in *B. subtilis*, several *E. coli/B. subtilis* shuttle vectors have been constructed based on the mentioned replicons to facilitate the plasmid propagation. Most of the constructed shuttle vectors are based on pUB110 or pBS72 origins of replication for *B. subtilis* and pBR322 for *E. coli* (198).
Table 1.3. Plasmids used as the parental vectors for construction of *E. coli*B. subtilis shuttle vectors are listed as stated by Schumann (198).

1.3. **Promoters used for gene expression in *B. subtilis***

Constitutive promoters, such as the promoter of *amyQ* from *B. amyloliquifaciens*, were among the first promoters exploited to express α-amylase, β-lactamase and human interferon α2 (IFN-α2) in *B. subtilis* (168-170). By expanding the knowledge of regulatory systems in *B. subtilis*, several inducible promoters have been later employed for gene expression in *B. subtilis* (Table 1.4). These inducible promoters could be classified into three major classes: (i) inducer-specific promoters, (ii) growth phase- and stress-specific promoters, and (iii) autoinducible promoters. Among them, inducer-specific promoters are the most widely used (198). So far, the expression systems in *B. subtilis* are mostly based on xylose or IPTG as the inducers. Basically, xylose-inducible expression systems comprise the promoter of the *xylAB* operon (*P*<sub>xylA</sub>). The *xylAB* operon encodes the components of the xylose utilization system in *B. subtilis*. The expression of *xylAB* is negatively regulated by a repressor, XylR. The inducer xylose binds and inactivates XylR (66). IPTG-inducible expression systems are based on *lac* operator and LacI, the repressor of the *lacZYA* operon in *E. coli* (71). IPTG-inducible *P*spac is a well-known
promoter in which the promoter of *B. subtilis* phage SPO-1 and *E. coli lac* operator are fused (258). IPTG inactivates LacI and thereby induces \( P_{spac} \) activity. Nevertheless, \( P_{spac} \) has some disadvantages including the high cost of IPTG and its toxicity. Besides, \( P_{spac} \) activity is not strong enough and not tightly-controlled for large-scale protein production (198). Hence, construction of the sugar-inducible expression systems are highly attended in recent years (163, 198). A summary of used promoters are listed in table 2.4.

The sugar-inducible promoters are generally activated by an activator or repressed by a repressor both of which regulate the gene expression at transcription initiation level. Prior to review the
carbohydrate uptake systems in *B. subtilis*, the promoter activation and repression must be explained.

### 1.3.1. Transcription initiation at the promoter

Transcription initiation requires the interaction of a multi-subunit DNA binding protein, *i.e.* DNA-dependent RNA polymerase (RNAP), with the promoter sequence (23). Three steps are defined for transcription initiation. Formation of a closed complex by binding of the RNAP to the promoter region, formation of an open complex by melting the DNA around transcription start site (also called isomerization), and finally transition from initiation to elongation phase in a process called promoter escape or clearance (235). RNAP is a holoenzyme (Eσ) consisting of a sigma factor (σ) and the multi-subunit core enzyme (E). In most of the bacteria, core enzyme comprises α₂, β, β’, and ω subunits. The α dimer subunits assemble a crab-claw structure formed by β and β’ subunits. The β subunit polymerizes the nascent RNA strand. The small ω subunit is likely a chaperone protein assisting the folding of β’ subunit (23). In *B. subtilis*, there is an extra auxiliary subunit, called δ, which is likely to be an integral RNAP subunit (47, 172). *In vitro* studies showed that this subunit increases the specificity of transcription in *B. subtilis* (98). Sigma factors have three major functions: (i) to ensure the recognition of specific promoter sequences, (ii) to position the RNA polymerase at the target promoter, and (iii) to facilitate the unwinding of the DNA duplex near the transcription start site. Different sigma factors are usually encoded by the genome of a bacterium each of which enables the recognition of different sets of promoters (23, 167, 246). For instance, *B. subtilis* contains at least 14 known variants of sigma factors (83, 117). Many promoters in *B. subtilis* including most of the sugar-inducible promoters are recognized by the housekeeping sigma factor, called σ^A_. The σ^A_-type promoters contain two principal elements called core promoter elements: -10 hexamer (or box), a.k.a. Pribnow box, and -35 hexamer. The -10 box (TATAAT) is located about 10 bp upstream of the transcription start site (shown by +1), while the -35 box (TTGACA) is placed 35 bp upstream of the transcription start site (Fig. 1.2) (23, 167, 247).
Fig. 1. 2. The schematic view of the interaction between RNA polymerase holoenzyme and a \( \sigma^A \)-type promoter (23).

The distance between -10 and -35 boxes, called spacer sequence, is 17 bp long in an optimal \( \sigma^A \)-type promoter (83). The domain 2 of the sigma factor binds to promoter -10 box and -35 box is recognized by the domain 4 of the sigma factor (48, 70). In addition to core elements, there are two extra elements in the promoter sequence. The first one is an AT rich sequence, called the UP element, where the C-terminus of the \( \alpha \) subunit (\( \alpha \text{CTD} \)) binds (54, 89, 184). The second extra element is called the extended -10 box, where the domain 3 of the sigma factor binds (70). By binding of the RNAP holoenzyme to the promoter sequence, the DNA strand is unwound from -10 to +2 positions to generate the open complex (23, 83). This isomerization, transition of the closed complex to the open complex, results in binding of the non-template strand to the domain 2 of the sigma factor. Next steps are initiation of RNA synthesizing and transcription elongation if the promoter clearance occurs (Fig. 2.3). However, the number of RNA polymerases and sigma factors in the cell are limited. For prudent distribution of the RNAP holoenzyme, some mechanisms regulate the transcription initiation. These include optimal sequence of the promoter core elements, presence of the anti-sigma factors, binding of small ligands such as ppGpp to RNAP, and transcription factors (23, 88, 167, 246). Among them, the sequence of the promoter core elements and transcription factors are more specific for the regulation of an operon. The conventional transcription factors are classified in two groups: transcriptional repressors and activators (88).
1.3.2. Transcription initiation repression

Some promoters require no additional factors for their activity due to the optimal sequence of their core elements. In general, the activity of such promoters is controlled by transcriptional repressors (77). Transcriptional repressors act in different ways (Fig. 1.3.A). The simplest way is the steric hindrance of RNA polymerase. In this case, the repressor binding site is often located between the core promoter elements or close to them. Binding of the repressor constraints the binding of RNAP to the promoter core elements (23, 183, 230). Binding of the LacI repressor to O₁ operator at lac promoter of *E. coli* is an example for this mechanism (191). In another case, the repressor binding site is upstream and downstream of the promoter core elements. Binding of the repressor molecules to their binding site is followed by protein-protein interactions which causes DNA looping. The DNA looping inhibits the formation of closed complex (23, 183, 230). Repression of the *gal* promoter by GalR in *E. coli* is a well-known example (68). Finally, repression by modulation of an activator or anti-activation happens when the repressor binding site overlaps an activator binding site (23, 183, 230). The latter mechanism is observed between cytidine catabolism regulator (CytR) and cyclic AMP receptor protein (CRP) in *E. coli* (229). The three mechanisms are depicted in Fig. 1.3.A.

1.3.3. Transcription initiation activation

Most of the promoters lack a good match to the consensus sequence of housekeeping promoter core elements. These group require ancillary proteins, known as transcriptional activators (77). In general, activators bind upstream of the target promoter and recruit RNAP by direct protein-protein interaction (10). The simple promoter activation is categorized to four mechanisms (3 mechanisms are shown in Fig. 1.3.B) (23). In class I activation, the activator binds upstream of the -35 box and interacts with αCTD of RNAP. The flexible linker of αCTD and αNTD enables the Class I activators to bind at different distances upstream of the -35. The activator binding site in class I activation is usually located near positions -61 to -91 (10, 23, 77). The most prominent example of this class is the CRP binding site at the lac promoter (51). In the second class, the activator binds directly adjacent to the -35 box. Thus, the activator directly
contacts domain 4 of the sigma factor (10, 23, 77). This is found in the $P_{RM}$ promoter of bacteriophage $\lambda$ where CI binding site is close to the promoter core (162). In the third class, the activator binds to the core promoter and changes the conformation of the promoter by twisting the DNA. This DNA twisting enables the promoter to be bound by a sigma factor (23). For instance, the MerR-type activators bind to the spacer sequence and twist the DNA to reorientate the -10 and -35, thereby the sigma factor can bind (22, 90). In the fourth mechanism, the activator modulates the repression in a process, called anti-repression (230). This was shown in the promoter of competence transcription factor (ComK) in $B. subtilis$. Binding of the ComK activator to the minor groove at $comK$ promoter results in physical displacement of the repressors Rok and CodY by which the repression effect will be removed (203). All of the mentioned mechanisms are simple activation and repression mechanisms. There are, however, other mechanism which have more complicated regulations (10, 23, 77, 88, 137, 183, 230).

1.4. Carbohydrate uptake systems in $Bacillus subtilis$

$B. subtilis$ is able to degrade several plant-derived polysaccharides by secretion of extracellular enzymes, such as $\alpha$-amylase ($amyE$) (216), levansucrase ($sacB$) (132), and levanase
The resulting oligo-, di- and monosaccharides are then transported into the cell and catabolized. At least 18 different mono- or disaccharides can be used by B. subtilis as a carbon source (113, 210). For uptake of carbohydrates, different transport systems can be employed by B. subtilis (summarized in Table 1.5). These carbohydrate uptake systems include: ATP-binding cassette (ABC), phosphoenolpyruvate (PEP): sugar phosphotransferase system (PTS), facilitators and secondary active transporters (44, 210). Among them, PTS is the main carbohydrate uptake system in B. subtilis (180, 237).

1.5. Phosphoenolpyruvate-dependent phosphotransferase system (PTS)

PTS is a phosphotransfer system by which a carbohydrate is simultaneously transported across the cytoplasmic membrane and phosphorylated (114). This carbohydrate uptake system comprises two general proteins, enzyme I (EI; 63 kDa) and a histidine-containing phosphocarrier protein (HPr; 9 kDa), as well as a multidomain sugar-specific transporter, called enzyme II (EII) (73, 165). The phosphoryl group transferred by PTS is originated from phosphoenol pyruvate (PEP). The EI protein is the first component of this cascade which becomes autophosphorylated using PEP as the phosphoryl donor. In the next step, EI phosphorylates the phosphocarrier HPr protein at His15. Finally, this phosphoryl group is transferred to the sugar specific EII located at the cytoplasmic membrane. The phosphorylated sugar is then catabolized in glycolysis in which two PEP will be generated (Fig. 1.4) (44, 75, 114, 176).
1.6. **PTS encoding operons and their specific regulators in *B. subtilis***

Generally, the operons encoding PTS in *B. subtilis* consist of one or two encoding genes for sugar-specific EII (transporter) and phosphosugar modifying enzymes (listed in Table 1.6). The PTS transporters are composed of three (or four) domains, where the soluble domains IIA and IIB being part of the phosphorylation chain, while IIC is the membrane-bound domain which transports the carbohydrate. Operons encoding PTS are usually regulated by their specific regulator encoded by a gene located within or outside the PTS operon (45, 180). These regulators function in different ways, such as transcription activation, transcription repression, and transcription antitermination (see Table 1.6). According to their function, transcriptional activators and repressors contain DNA binding domains, while antiterminators contain RNA binding domains (45). Some of the regulators are directly activated in the presence of their phosphosugar. For instance, the repressor of the trehalose PTS-encoding operon, TreR, loses its DNA binding affinity by trehalose 6-phosphate (26). Besides, the activator of the maltose PTS-encoding operon, MalR, is supposed to bind its operator only in a complex with maltose 6-phosphate (253). Other regulators contain extra duplicated PTS-regulatory domains (PRD). *B. subtilis* 168 contains eight PRD-containing regulators including PRD-containing antiterminators.
(GlcT, LicT, SacT, and SacY, a.k.a. BglG/SacY family) and PRD-containing activators (LicR, MtlR, and ManR, a.k.a. DeoR-type activator family, and LevR) (79, 208, 231). Phosphorylation or dephosphorylation of the PRD domains activates or deactivates the regulator. However, this activation mechanism is somewhat different between the PRD-containing activators and antiterminators.

* The PRD-containing regulators are shown by bold letters.

1.6.1. Regulation of GlcT and other PRD-containing antiterminators

Glucose is the preferred carbon and energy source for many bacteria. In B. subtilis, glucose is mainly taken up via a phosphoenolpyruvate-dependent phosphotransferase system encoded by ptsGHI operon (Fig. 1.5.A). The ptsG gene encodes for specific EIICBA\textsuperscript{Glc} transporter, while ptsH and ptsI encode for general HPr and EI proteins of the PTS pathway (73, 74). The EIICBA\textsuperscript{Glc} protein consists of two hydrophilic domains, EIIB\textsuperscript{Glc} and EIIA\textsuperscript{Glc}, which are involved in the phosphorylation of glucose and of domain C, a membrane-bound domain, which transports glucose (215). The ptsHI genes are constitutively expressed by a promoter, P\textsubscript{ptsHI}, located downstream of ptsG. Therefore, general proteins of the PTS pathway, \textit{i.e.} HPr and EI, are
always present in the cytoplasm. In addition to $P_{ptsHI}$, an inducible promoter, denoted $P_{ptsGHI}$, directs the expression of the $ptsGHI$ operon (Fig. 1.5.A).

![Diagram of genetic organization and regulation of the $ptsGHI$ operon and its antiterminator, GlcT. (B) Deactivation of GlcT by EII$^{Glc}$ in the absence of glucose. (C) Activity of GlcT in the presence of glucose. (CM: Cytoplasmic membrane; EI: Enzyme I; G6P: Glucose 6-phosphate; HPr: Histidine-containing phosphocarrier protein; PRD: PTS-regulatory domain; RBD: RNA binding domain) (192).]

$P_{ptsGHI}$ is regulated by GlcT antiterminator. This protein belongs to the BglG/SacY antiterminator family in $B.\ subtilis$. The $glcT$ gene is located upstream of the $ptsGHI$ operon (74, 212). GlcT consists of an N-terminal RNA binding domain, and the PRDI and PRDII domains.
Phosphorylation of the PRD domains of GlcT modulates the protein activity in response to the availability of the glucose (7). In the absence of glucose, GlcT is phosphorylated by EIIB\textsubscript{Glc} in PRDI (Fig. 1.5.B). This phosphorylation deactivates GlcT. In this case, the transcription of \textit{ptsGHI} operon is early terminated due to the presence of a terminator structure in the leader sequence of \textit{ptsG}. This terminator is overlapped by an inverted repeat, called ribonucleotide antiterminator (RAT). This overlap forms a protein-dependent riboswitch. When glucose is present in the extracellular milieu, uptake of glucose leads to dephosphorylation of EII\textsuperscript{Glc} (Fig. 1.5.C). This dephosphorylation competes with the phosphorylation of GlcT by the EII\textsuperscript{Glc}. Thus, GlcT becomes active and binds to RAT. Upon binding of GlcT, a new stem-loop structure forms preventing the early transcription termination of the \textit{ptsGHI} mRNA (7, 123, 190, 212). In addition to EII\textsuperscript{Glc}-dependent phosphorylation in PRDI, there is a second phosphorylation in PRDII domain of GlcT mediated by HPr(H15~P). The PRDII phosphorylation slightly stimulates the GlcT activity. In other words, GlcT is still active when PRDII is dephosphorylated; however, the full activity is only observed when PRDII is phosphorylated and PRDI is dephosphorylated (192). Similarly, all members of the BgIG/SacY antiterminator family of \textit{B. subtilis} are negatively affected by the cognate transporter. However, the role of phosphorylation via HPr(H15~P) varies among these antiterminators (231). Similar to GlcT, SacY is still functional in the absence of HPr (36). In contrast, other transcriptional antiterminators such as LicT or SacT absolutely require the phosphorylation of the PRDII by HPr(H15~P) for activity (3, 45, 115, 136).

1.6.2. Regulation of PRD-containing activators in \textit{B. subtilis}

PRD-containing activators in \textit{B. subtilis} are basically divided into two groups. The first group is called DeoR-type activators including MtlR, ManR, and LicR. The second group with LevR, as the only member, comprises NifA/NtrC-type activators. The DeoR-type activators usually interact with the $\sigma^A$-containing RNAP holoenzyme, whereas LevR interacts with RNA polymerase containing $\sigma^+$ (45, 61). Therefore, domain organization in these groups are different (Fig. 1.6) (79). DeoR-type activators contain a helix-turn-helix (HTH) motif in their N-terminus resembling the DNA binding domain in transcriptional activators of the \textit{E. coli} DeoR family.
This DNA binding domain is followed by two PRDs each of which contains two conserved histidyl residues. The PRDs are followed by an $\text{EIIB}^{\text{Gat}}$-like domain containing a conserved cysteyl residue and an EIIA-like domain belonging to the mannitol/fructose class PTS (45, 79).

Early knowledge dealing with regulation of a DeoR-type activator was achieved by studying *Geobacillus stearothermophilus* MtlR. This DeoR-type activator is phosphorylated by HPr(H15~P) in PRDII which activates MtlR. In the absence of mannitol, domain B of EII$\text{CBA}^\text{Man}$ phosphorylates the EIIA$^\text{Mtl/Fru}$-like domain of MtlR to deactivate it (93, 94). Similar to *G. stearothermophilus* MtlR, phosphorylation by HPr(H15~P) is essential for the activity of ManR, while removal of EII$\text{CBA}^\text{Man}$ leads to constitutive activity of the *manPA* promoter (214).

LicR in *B. subtilis* is regulated by the same mechanism (221). Lately, it has been shown that the $\text{EIIB}^{\text{Gat}}$-like domain of *B. subtilis* MtlR also interacts with the EIIA$^\text{Mtl}$ (107). Phosphorylation of LevR is different from DeoR-type activators. This NifA/NtrC-type activator, LevR, is the best studied PRD-containing activator in *B. subtilis*. LevR contains an N-terminal helix-turn-helix motif followed by a NifA/NtrC-like domain. The latter domain probably interacts with RNAP associated with $\sigma^I$ (45, 147). The central NifA/NtrC-like domain is followed by a complete PRD.

---

**Fig. 1.6**. Domain organization of the PRD-containing transcription activators. HTH represents helix-turn-helix motif in the DNA binding domain (45, 107, 213).
containing two conserved histidyl residues. There is also another truncated PRD containing only one conserved histidyl residue at the C terminus of LevR. Between the two PRDs, EIIA\textsuperscript{Man} and EIIB\textsuperscript{Gat} like domains are located (45). HPr(H15~P)-mediated phosphorylation occurs in the EII\textsuperscript{Man}-like domain which positively regulates the activity of LevR. In the absence of fructose, the second phosphorylation in PRDII inactivates LevR. This phosphorylation is mediated by EIIB\textsuperscript{Lev} (144, 211). Briefly, the PRDI domain in PRD-containing antiterminators is phosphorylated by specific transporter, while EIIA- and EIIB-like domains in PRD-containing activators interact with the specific transporter domains. The role of PRDI in the PRD-containing activators remains unknown. It is supposed that PRDI might transfer the signal from PRDII to the DNA binding domain (45).

1.7. PTS and CcpA-dependent carbon catabolite repression in *B. subtilis*

PTS is not only serving as a carbohydrate transport system, but also as a signal transducer for carbon catabolite repression (CCR) (209). In fact, the general PTS component, HPr, plays an important role in carbon catabolite repression in *B. subtilis*. HPr contains two phosphorylation sites including histidine 15 and serine 46. Histidine 15 is the PEP-dependent phosphorylation site transferring the phosphoryl group between EI and EII (114). In contrast, Serine 46 is phosphorylated in an ATP-dependent reaction by a homohexameric enzyme, called HPr kinase/phosphorylase (HPrK/P; 34 kDa) (65, 182). HPrK/P is a bifunctional enzyme which phosphorylates HPr-Ser\textsuperscript{46} at a high concentration of fructose 1,6-bisphosphate (FBP), while its phosphorylase activity is stimulated by a high inorganic phosphate concentration inside the cell caused by nutrient limitation (182). The presence of glucose or a PTS sugar in the nutrient medium results in a high level of FBP which is an intermediate product of glycolysis. HPr(S46~P) act as an effector for the pleiotropic transcription regulator, catabolite control protein A (CcpA) (45, 139). CcpA is a master transcription regulator which binds to different operons in *B. subtilis* and activates or represses the expression of these operons (204). Binding of the CcpA (36 kDa) dimer to its binding site is triggered in the presence of HPr(S46~P). Interestingly, the interaction between CcpA and HPr(S46~P) is also enhanced by the presence of FBS and glucose 1-phosphate (Fig. 1.7.A) (45, 75, 139). Rather than HPr(S46~P), another cofactor protein can
trigger the binding of CcpA to the DNA in *B. subtilis*. Catabolite repression HPr (Crh) has 45% identity to the HPr sequence; however, it lacks the histidine 15 residue. Therefore, Crh is unable to participate in the phosphoryl transfer cascade. In contrast, Crh can be phosphorylated by HPrK/P similar to HPr-S46 and replace it in the CcpA-dependent CCR (Fig. 1.7.B) (64, 148). Formation of the CcpA-Crh(S46~P) complex is not influenced by the glycolytic intermediates. Besides, binding of Crh(S46~P) to CcpA is four fold weaker than HPr(S46~P) (75). Recently, it has been found out that the Crh phosphorylation state plays an important role in the regulation of methylglyoxal synthase (MgsA) (Fig. 1.7.B) (122). MgsA catalyzes the production of methylglyoxal from dihydroxyaceton phosphate (DHAP), an intermediate product of glycolysis. At a low level of FBP, the unphosphorylated form of Crh interacts with MgsA and inhibits its activity. On the contrary, the elevated level of FBP pool in the cell leads to phosphorylation of Crh by HPrH/P. This phosphorylation relieves MgsA from Crh-mediated inhibition. Since the produced methylglyoxal is highly cytotoxic it will be excreted or probably converted to pyruvate (122).

![Fig. 1.7](image)

**A** Carbon catabolite repression in *B. subtilis*. (B) The role of Crh in regulation of methylglyoxal production and CcpA-dependent catabolite repression (FBP: Fructose 1,6-bisphosphate; DHAP: dihydroxyaceton phosphate; GAP: Glyceraldehyde 3-phosphate) (75, 122).

After formation of the CcpA-HPr(S46~P) or CcpA-Crh(S46~P) complex, this complex binds to a specific binding site in the target promoter region. This specific binding site is called catabolite
responsive element (cre) (240). Most of the cre sites are located at the promoter core elements or upstream of the promoter core elements. However, there are also some examples where the cre site is located at the 5’UTR region of mRNA or even inside the coding sequence (61). Several bioinformatics and practical analysis revealed the consensus sequence of cre comprising WTGNAARCGNNNCA sequence (152). Recently, a detailed comparison of the cre sites in the genome of B. subtilis showed two groups of functional cre sites harboring the consensus sequences WTGNAANCGNWWNCA and WTGAAARCGYTTWNN (61). Regarding the position of the cre site, binding of the CcpA complex can repress or activate the operon. For ackA (acetate kinase), pta (phosphotransacetylase), and ilv-leu (biosynthesis of branched-chain amino acids) genes, the cre site is located upstream of the promoter core elements and activates their gene expression (178, 200, 224, 227). These genes are required for the excretion of acetate when the cells are grown in the excess of carbon source. The cre site located inside the promoter core elements or downstream of the promoter region can repress gene expression by steric hindrance mechanism or elongation roadblock, respectively (45, 61).

1.8. CcpA-independent carbon catabolite repression

1.8.1. Catabolite control mediated by catabolite control proteins

In addition to CcpA-dependent CCR in B. subtilis, many genes are regulated by other catabolite control proteins, such as CcpB, CcpC, and CcpN. CcpB is a paralogous protein of CcpA and regulates some operons including gnt, xyl, and fad genes. The latter genes encode the fatty acid degradation (30, 61). CcpC represses the citB and citZCH genes encoding the first three steps of the TCA cycle (106). CcpN represses pckA encoding the phosphoenolpyruvate carboxykinase and gapB encoding the glyceraldehyde-3-phosphate dehydrogenase during glycolysis. In fact, CcpN is active when the cells are growing on a glycolytic substrate, even if the medium also contains a gluconeogenic substrate (199). CggR is another regulatory protein influencing the central glycolytic genes. This protein represses the gapA operon, i.e. cggR-gapA-pgk-tpi-pgm-eno. The gapA operon encodes the enzymes responsible for the conversion of three-carbon intermediates of glycolysis. FBP is an inhibitor of CggR (46, 140).
1.8.2. Catabolite control mediated by HPr(H15~P)

The phosphorylated HPr-H15 can also play an important role in the carbon catabolite repression of many operons. HPr-H15 is not only a phosphocarrier protein for the specific enzyme II of many PTS systems, but also it is capable of phosphorylation of the glycerol kinase, RNA-binding antiterminators and DNA-binding transcription activators of the PTS-sugar utilization systems (45, 61, 75).

1.8.2.1. Inducer exclusion in glycerol utilization system

In *B. subtilis*, glycerol is taken up by a facilitator, called GlpF, and converted to glycerol 3-phosphate by the glycerol kinase (GlpK). The *glpFK* operon is induced by binding of glycerol 3-phosphate and GlpP, an antiterminator, to the mRNA leader sequence of *glpFK*. This binding prevents the early transcription termination. Glycerol kinase (GlpK) is activated by a phosphoryl transfer from HPr(H15~P) (Fig. 1.7.A). In the presence of glucose, HPr(H15~P) is mainly dephosphorylated by EIICBA\textsubscript{Glc} leading to prevention of GlpK phosphorylation. The unphosphorylated GlpK is less active than its phosphorylated form. Therefore, transcription of *glpFK* operon is terminated due to the low amount of glycerol 3-phosphate in the cell. This mechanism of repression is called inducer exclusion (38).

1.8.2.2. Induction prevention of the PRD-containing regulators

Several PTS operons are regulated by transcription regulators comprising PTS-regulatory domains (PRD). The activity of these PRD-containing regulators (activator or antiterminator) is modulated by PTS-dependent phosphorylation of their PRDs. This type of regulation is based on the sugar-specific EII and HPr(H15~P). In the absence of sugar, the related specific EII phosphorylates PRDI in antiterminators or EIIA- and EIIB-like domains in activators. In addition to EII-dependent phosphorylation, HPr(H15~P) also catalyzes the phosphorylation of PRDII in the absence of glucose. HPr(H15~P) is efficiently used in the presence of a preferred PTS-
carbohydrate, such as glucose. This constitutes a CCR mechanism that downregulates the activities of PRD-containing regulators (45, 61, 75).

1.9. Mannitol utilization system in *B. subtilis*

Mannitol is taken up via a PTS in *B. subtilis*. In mannitol PTS pathway, mannitol passes through the domain C and becomes phosphorylated by the domain B of membrane-bound EIICB\(^{\text{Mtl}}\). This phosphate is provided by the cytoplasmic EIIA\(^{\text{Mtl}}\) protein which has been already phosphorylated by HPr(H15~P). The mannitol 1-phosphosphate dehydrogenase enzyme converts the uptaken mannitol 1-phosphate to fructose 6-phosphate which is an intermediate compound of glycolysis pathway. The mannitol utilization system is encoded by the *mtlAFD* operon located at 449.72 – 452.73 kb of the chromosome of *B. subtilis* 168 (Fig. 1.8). The *mtlA* gene (1437 bp) is the first gene of the operon encoding the EIICB\(^{\text{Mtl}}\) protein (50 kDa) (9, 117). The *mtlF* gene (432 bp) encodes the cytoplasmic phosphocarrier protein, EIIA\(^{\text{Mtl}}\) (15 kDa) (9, 107). Finally, the *mtlD* gene (1122 bp) encodes the mannitol 1-phosphate dehydrogenase enzyme (41 kDa) (9, 117). Transcription of the operon is activated by the activator, MtlR (78 kDa). The *mtlR* gene (2085 bp) encoding the activator is located 14.1 kb downstream of the *mtlAFD* operon. Interestingly, expression of *mtlAFD* operon is induced by glucitol in addition to mannitol which is the main inducer. Besides, the presence of mannitol 1-phosphate dehydrogenase is essential for assimilation of glucitol (239). Glucitol is a non-PTS sugar taken up by a H\(^+\)-symporter (GutP) and oxidized to fructose by glucitol dehydrogenase (GutB) inside the cytoplasm. However, a weak uptake of glucitol by mannitol-specific EII has been already observed (28).

![Fig. 1.8. Genetic map of the mtl operon and its regulator on the chromosome of B. subtilis 168.](image-url)
1.10. Aim of the study

In order to construct an expression vector for heterologous and homologous genes in \textit{B. subtilis} based on low cost inducer, the mannitol utilization system was chosen. In \textit{B. subtilis}, mannitol is taken up via a phosphoenolpyruvate-dependent phosphotransferase system (PTS). So far, regulation by PRD-containing antiterminators has been mainly studied in \textit{B. subtilis}. Among the PRD-containing activators, regulation of LevR and LicR has been also investigated. Besides, the mannose PTS in \textit{B. subtilis} has been recently characterized and its regulation is being studied. Prior to this study, activation of the \textit{mtlAFD} operon, encoding mannitol utilization system, and the location of its activator, \textit{mtlR}, has been reported. Nevertheless, the exact regulation of the \textit{mtlAFD} operon as well as its activator encoding gene (\textit{mtlR}) is unknown. Thus, the promoter structure of the \textit{mtlAFD} operon and \textit{mtlR} in \textit{B. subtilis} will be characterized in this study. Next, regulation of these promoters in several mannitol utilization deficient mutants will be studied. Also, regulation of MtI\text{R}, as a PTS-containing regulator, will be investigated. A challenge in application of a sugar-inducible system is caused by glucose catabolite repression. Therefore, catabolite repression of the promoters of mannitol PTS encoding operon and its activator will be investigated. Finally, a highly inducible expression vector based on mannitol will be constructed which can be used for expression of heterologous and homologous genes in \textit{B. subtilis}.

</tbody>
</table>

a The numbers are showing the base pair position with respect to start codon of the wild type gene.
b The fusion PCRs are shown by (F.) sign.
*[→*]: the asterisk and bracket show the base pair exchange in the sequence.

2.9. **Growth conditions**

Propagation of the desired plasmid was performed by *E. coli* JM109 or *E. coli* DH5α. For this purpose, a single colony of an *E. coli* transformant was cultivated in a glass tube with 5 ml LB containing the relevant antibiotic. The *E. coli* culture was incubated overnight at 37°C and used for plasmid isolation.

Unless otherwise specified, *B. subtilis* 3NA was used as a host microorganism. Knock-out mutants were selected on LB agar, supplemented by erythromycin (5 μg/ml) or chloramphenicol (5 μg/ml). Knock-out mutations were confirmed by cultivating the mutants in broth I with no trisodium citrate. Depending on the mutation, glucose was also replaced with 1% (w/v) sterile-filtered mannitol or glucitol. Tryptophan was added to the broth I for tryptophan auxotrophic *B. subtilis* 168 and its derivatives. All of the strains were incubated overnight at 37°C under a shaking condition at 200 rpm to compare the turbidity of the mutants cultures with the wild type strain as a control.

The activity of the promoters was measured by cultivation and induction of the *B. subtilis* 3NA harboring the desired plasmid in LB. For this purpose, 85 ml LB medium in a 500 ml Erlenmeyer flask was inoculated with an overnight culture in a dilution of 1:50 and incubated at 37°C under shaking (200 rpm). Then, aliquots of 8 ml with an OD$_{600}$ of 0.4 were divided into 100 ml Erlenmeyer flasks and different carbohydrates, *i.e.* mannitol, mannitol + glucose, glucose, glucitol, glucitol + glucose, were subsequently added to a final concentration of 0.2% (w/v). Cultures were harvested 1 h after the addition of sugars and used for the β-galactosidase enzyme assay. As a defined medium, Spizizen’s minimal salts (SMS) supplemented by trace elements was also used to measure the promoter activities in the same procedure. All of the experiments were repeated at least 3 times and mean values were used for comparison.
2.10. DNA manipulation

2.10.1. DNA isolation

2.10.1.1. Plasmid isolation by alkaline lysis

Isolation of the plasmid from *E. coli* transformants was performed according to the method of Lee and Rashed (1990) with a slight modification (130). A single colony of *E. coli* transformants was inoculated into 5 ml LB broth and incubated overnight at 37°C. Afterwards, the overnight culture was centrifuged for 5 min at 4,500 rpm (Megafuge), and the pellet was resuspended in 200 μl resuspension buffer. Next, 300 μl of lysis solution was added to the cell suspension. The lysate was gently inverted 4 to 5 times and remained up to 5 min at room temperature. Subsequently, 400 μl of neutralization solution was added to the lysate and mixed thoroughly. The neutralized mixture was centrifuged for 10 min at 13,000 rpm (Microcentrifuge) and 600 μl of the clear supernatant was added to 600 μl of isopropanol in a new Eppendorf tube. Having thoroughly mixed, the mixture was centrifuged for 10 min at 13,000 rpm (Microcentrifuge) and the pellet washed twice with 70% and 100% ethanol, respectively. The pellet was air-dried and resuspended in 30 to 50 μl ddH₂O.

2.10.1.2. Plasmid isolation by QIAprep® Spin Miniprep Kit

The plasmid DNA used for cloning, sequencing and storage were purified by QIAprep® Spin Miniprep Kit. The procedure was performed according to the manufacturer’s manual. Plasmid isolation from *B. subtilis* was preceded by incubation of the bacterial suspension in resuspension buffer containing 20 mg/ml lysozyme in an Eppendorf thermomixer for 30 min at 37°C and shaked at 750 rpm. The protoplast suspension was then mixed with lysis solution and the plasmid isolation was accomplished according to manufacturer’s manual. Plasmid DNA was finally eluted by 50 μl ddH₂O.
2.10.1.3. **Isolation of chromosomal DNA by DNeasy Blood & Tissue Kit**

Isolation of the chromosomal DNA from *B. subtilis* was carried out using DNeasy Blood & Tissue Kit (Qiagen). An overnight culture of *B. subtilis* in LB medium (2 ml, 4 OD$_{600}$) was centrifuged for 10 min at 4,500 rpm (Megafuge). The pellet was then resuspended in 180 µl resuspension buffer containing 20 mg/ml lysozyme and incubated in an Eppendorf thermomixer for 30 min at 37°C and shaked at 750 rpm. Further steps were performed according to the manufacturer's instructions. For final elution, 200 µl ddH$_2$O was used.

2.10.2. **PCR**

2.10.2.1. **DNA amplification**

To amplify the desired gene from the *B. subtilis* 168 chromosome or a plasmid, polymerase chain reaction (PCR) was carried out using Phusion® Hot Start II, *Pfu* DNA Polymerase or High Fidelity Polymerase. All of the PCRs were performed in a final volume of 100 µl according to the Table 2.3.

<table>

*5x reaction buffer contains 7.5 mM MgCl$_2$ used for reactions by Phusion® Hot Start II, while 10x reaction buffers containing 20 mM MgSO$_4$ and 15 mM MgCl$_2$ used for *Pfu* DNA Polymerase and High Fidelity Polymerase, respectively.*
The PCR was performed in a MJ Research Peltier thermocycler PTC-200 according to the Table 2.4. The amplified fragments were afterwards analyzed on the 0.8% (w/v) agarose gel in order to check the length of the fragment as well as its purity.

**2.10.2.2. Fusion PCR**

Two DNA sequences were fused to each other using fusion PCR. At first, the selected genes were separately amplified by primary oligonucleotides (a & b; c & d; Fig. 2.1). The reverse primer of upstream gene with respect to the fusion orientation and the forward primer of downstream gene included identical overhang sequences shown as in Fig. 2.1 by dashes with at least 17 bp length. After purification of the primary PCRs products, 1 µl of each PCR product was mixed in a new PCR without oligonucleotide primers. The annealing temperature was calculated according to the melting temperature of the identical sequence. After 10 cycles, the forward primer of the upstream gene and the reverse primer of the downstream gene were added and the PCR was continued for another 25 cycles with the annealing temperature of the primers (oligonucleotides a and d; Fig. 2.1).

![Fig. 2.1. Schematic view of a fusion PCR is shown. PCRs using oligonucleotides a/b and c/d was followed by final PCR using a/d oligonucleotides and the primary PCRs products. The dashes show the identical sequences with at least 17 bp length.](image)
2.10.2.3. Colony PCR

Deletion and insertion of the chromosomal DNA in *B. subtilis* transformants were rapidly investigated by colony PCR. A single colony of *B. subtilis* was suspended in 100 µl sterile water and boiled for 10 min. The suspension was subsequently centrifuged for 3 min at 13,000 rpm (Microcentrifuge). 10 µl of the clear supernatant was used as the template in the PCR as described in 3.10.2.1. The PCR product was finally analyzed on agarose gel.

2.10.2.4. Purification of PCR products

PCR fragments were purified by the columns of GFX™ PCR DNA and Gel Band purification kit (GE Healthcare) according to manufactures’ instructions.

2.10.3. Hybridization of complementary oligonucleotides

Short fragments of dsDNA were constructed by hybridization reaction in which 5 µl of two complementary oligonucleotides (100 pmol/µl) were mixed with 1:1 ratio. The oligonucleotide mixture was denatured for 5 min at 92°C followed by annealing for 10 min at 65°C. The reaction was subsequently cooled to 4°C for 1 – 2 min and kept on ice. 5 µl of the dsDNA was used for the digestion reaction.

2.10.4. Restriction digestion of PCR fragments and plasmids

Plasmids and PCR products were digested in a final volume of 20 µl. Either 7 µl of isolated plasmid or 5 µl of PCR fragment (approx. 0.5 µg) were digested by adding 2 µl of 10x restriction buffer and 1 µl of restriction enzyme (3 – 5 U). The reaction was incubated 1 to 2 h at the relevant temperature. In the case of double digestion, the DNA was first digested with an enzyme followed by isopropanol precipitation (see below). The precipitated DNA was resuspended in ddH₂O and subjected to the second restriction enzyme with a final volume of
20 µl. Finally, the digested DNA was loaded to an agarose gel in order to cut and purify the desired fragment.

2.10.5. Isopropanol precipitation of DNA

To precipitate DNA, 2 µl sodium acetate (3 M, pH 6.3) and 20 µl isopropanol were added to 20 µl DNA solution and mixed thoroughly. After incubation for 5 min at room temperature, the solution was centrifuged for 5 min at 13,000 rpm (Microcentrifge). The supernatant was discarded and pellet was washed twice by 40 µl 70% ethanol and 40 µl 100% ethanol. Finally, the pellet was air-dried at room temperature and dissolved in relevant amount of ddH₂O.

2.10.6. Agarose gel electrophoresis

Confirmation of the correct PCR product, plasmid restriction pattern, or to isolate restriction fragments were performed by agarose gel electrophoresis. By this method, the DNA fragments are separated by the electric field according to their size. The gel was prepared by addition of 0.46 g agarose to 60 ml TAE buffer (short gel) and 1.2 g agarose to 150 ml TAE buffer (long gel) followed by boiling. Finally, 2.4 µl and 6 µl ethidium bromide (10 mg/ml) were added to the short and long gels, respectively, and poured into the gel tray. The DNA sample was mixed with 10x sample loading buffer and separated in TAE running buffer through agarose gel. For size determination, 3 µl of 1 kb DNA ladder (Fermentas) were loaded on a separate lane. Long gels were run by 100 – 120 V and short gels by 80 V. The DNA bands were detected by UV light with 302 nm wave length.

2.10.7. Purification of the DNA from agarose gel

After separating the DNA fragments on the agarose gel, the desired band was cut out under the UV light (366 nm) with a scalpel. The cut gel fragment was immersed in binding buffer
and melted at 70°C. The DNA was purified by the column of “GFX™ PCR DNA and Gel Band purification kit” (GE Healthcare) according to manufactures’ instructions.

2.10.8. Alkaline phosphatase treatment

The ligation efficiency of the digested vectors at a single restriction site was increased by the application of alkaline phosphatase (Roche). This enzyme removes the phosphate group from the 5’-end of the DNA, thereby inhibiting self-ligation of the parental vector. For this reaction, 25 μl purified vector DNA was mixed with 3 μl 10x buffer and 2 μl alkaline phosphatase (20 U/μl). The reaction incubated for 30 minutes at 37°C. Finally, the DNA was purified by the GFX™ PCR DNA and Gel Band purification kit and used for ligation.

2.10.9. DNA concentration

Concentration of the PCR products, digested DNA, and plasmids were measured using a NanoPhotometer (IMPLEN GmbH) at 260 nm. 1 OD_{260} corresponds to 50 μg/ml dsDNA.

2.10.10. Ligation

Insertion of the desired gene into the plasmid vector was carried out by ligation. The desired insert and vector were mixed with 2 μl of the ligation buffer containing ATP and ddH₂O in a final volume of 19 μl. Finally, 1 μl of T4 DNA ligase (Roche) was added to DNA solution. Cohesive end ligation was performed at 4°C, whereas the blunt end was incubated overnight at room temperature.
2.10.11. DNA sequencing

The sequencing of DNA was performed according to Sanger’s method (187) using a 5’-end Cy5-labeled oligonucleotide and ALF express Genetic analyzer (Amersham Pharmacia Biotech). As the template, desired plasmids were isolated by Miniprep Kit and precipitated by sodium acetate-isopropanol. After isopropanol precipitation, 5 to 10 μg plasmid DNA was dissolved in 10 μl ddH₂O. Afterwards, 2 μl of Cy5-labeled oligonucleotide (10 pmol/μl) and 1.5 μl NaOH (1 M) were added to 10 μl ddH₂O. The mixture was incubated for 5 min at 65°C followed by cooling at 37°C water bath. Next, 1.5 μl HCl (1 M) and 2 μl annealing buffer (AutoRead Sequencing kit, Amersham Pharmacia Biotech) were added to the mixture. Having incubated for 10 min at 37°C, the reaction was finally kept for 10 min at room temperature. Subsequently, 1 μl extension buffer and 3.5 μl DMSO were added to the reaction. Four 5.4 μl aliquots of the reaction mixture were divided into four Eppendorf tubes each of which contained 2 μl enzyme mix (1 μl T7 DNA polymerase + 1 μl enzyme dilution buffer with a concentration of 4 U/μl) and 3 μl ddNTP solution which contained either ddATP, ddCTP, ddGTP or ddTTP in combination with other three dNTPs. The reaction was incubated for 5 minutes at 37°C and stopped by the addition of 6 μl stop solution. After incubation for 3 min at 80°C, the samples remained on ice before loading on the gel. The sequencing gel was prepared according to manufactures’ instructions (Amersham Pharmacia Biotech). TBE buffer (0.5x) was used as running buffer. To analyze the sequences, 5 μl of each reaction was loaded to the wells of the gel.

2.11. RNA manipulation

2.11.1. RNase-free equipment

During RNA-based experiments, all of the applied materials and equipment were prepared RNase-free. To do so, the solutions and glass wares were treated with 0.1% (v/v) DEPC and incubated overnight at 37°C. Subsequently, they were autoclaved for 45 min until the DEPC scent was gone. The instruments which could not be autoclaved were swabbed by RNase AWAY®.
2.11.2. RNA isolation

20 ml of LB supplemented with 10 μg/ml spectinomycin was inoculated by overnight culture (400 μl) and incubated at 37°C. At the OD$_{600}$ of 0.4, the bacterial culture was divided into two 10 ml aliquots and one of them was induced by 0.8% (w/v) mannitol, while the other one incubated uninduced. The bacterial cultures were harvested 1 h after the addition of mannitol, and centrifuged for 5 min at 4,500 rpm (Megafuge). The supernatant was discarded to reduce the rest volume to less than 80 μl. Finally, total RNA was then extracted using RNeasy Mini Kit (QIAGen) according to manufactures’ instruction.

2.11.3. Formaldehyde agarose gel electrophoresis

To control the quality of the extracted RNA, the isolated RNA was loaded on a 1.2% (w/v) formaldehyde agarose gel. The gel was prepared by dissolving of 0.6 g agarose in 45 ml DEPC-treated ddH$_2$O and 5 ml of 10x formaldehyde gel buffer. The suspension was boiled and cooled to 60°C, and 0.9 ml formaldehyde (37%) was added. The solution was poured on a small gel tray. After solidification, the gel was equilibrated for 30 min in formaldehyde agarose running buffer. Next, 3 μg RNA was mixed with 5x sample loading buffer, heated for 15 min at 65°C, and immediately cooled on ice prior to electrophoresis. The electrophoresis was carried out by 100 V for 5 min which was then reduced to 60 V as long as the bromophenol blue bands passed the two third of the gel length. The formaldehyde agarose gel was stained in 200 ml formaldehyde running buffer containing 0.5 μg/ml ethidium bromide for 1 h at room temperature. Finally, the gel was observed under the UV light (302 nm).

2.11.4. Isopropanol precipitation of RNA

50 μg of isolated RNA dissolved in 100 μl DEPC- treated ddH$_2$O was mixed with 10 μl of sodium acetate (3 M, pH 6.3) and 220 μl of ethanol (100%). The mixture was incubated overnight at -20°C and then centrifuged for 10 min at 13,200 rpm (Microcentrifuge). After
discarding the supernatant, the pellet was washed twice with 100 µl ethanol and dried at room temperature. The pellet was finally dissolved in 5 µl DEPC-ddH₂O.

2.11.5. Primer Extension

Cy5-labeled oligonucleotides were used to determine the transcription start site of the desired promoters in this study. As described in section 3.12.2, the total RNA (50 µg) was isolated and precipitated by isopropanol and finally resuspended in 5 µl ddH₂O. To inhibit RNase activity, 0.5 µl RNasin® Ribonuclease inhibitor (Promega, 40 U/µl) was added to the 5 µl total RNA, followed by denaturation at 65°C for 3 min and cooling on ice. Subsequently, 0.5 µl labeled oligonucleotide (10 pmol/µl), namely s5959 or s5960, and 2 µl of 5x AMV-RT buffer were added to the RNA sample. The hybridization was performed for 20 min at 54°C (s5959) or 52°C (s5960). Afterwards, the RNA-oligonucleotide hybrid was cooled gradually within 5 minutes to room temperature. The reverse transcription reaction was started by the addition of 1µl dNTP (10 mM) and 1 µl Avian Myeloblastosis Virus Reverse Transcriptase (AMV-RT; 20 U/µl). The reaction was incubated for 1 h at 42°C and stopped by the addition of 5 µl of stop solution from the AutoRead sequencing Kit (Amershan Pharmacia Biotech) and incubation for 3 min at 80°C. The reactions were kept on ice or frozen at -20 before further analysis. To compare the obtained band of reverse transcription with the sequencing results, 5 µl of each reaction was loaded onto the ALFexpress DNA polyacrylamide sequencing gel. The same labeled oligonucleotide was used in the sequencing reaction of the desired plasmid.

2.12. Transformation of *E. coli* JM109

*Escherichia coli* JM109 was transformed by the heat shock method (186). Competent cells were prepared by inoculation of 100 ml LB with an overnight culture (1:100) and incubation of the bacterial culture at 37°C. At the OD₆₀₀ of 0.35 to 0.40, the bacterial culture was centrifuged for 10 min at 4500 rpm in a SORVALL SS34 rotor. The cells were then resuspended in 4 ml ice-
cooled TSS. The ligation reaction was added to 200 μl of competent cells and incubated on ice for 30 min. Alternatively, the competent cells could be stored at -70°C and thawed before addition of the ligation mixture or desired plasmid. The bacteria-DNA mixture was heat shocked for 60 sec at 42°C followed by further incubation on ice for 2 – 3 min. 2 ml of LB medium was added to the bacteria and the bacterial culture was incubated in a roller drum for 30 min at 37°C. After incubation, the culture was centrifuged for 5 min at 4500 rpm (Megafuge) and the pellet was resuspended in 100 μl of the remaining supernatant. The bacterial suspension was plated onto LB agar plates containing the relevant antibiotic. As a positive control, the competent cells were transformed with pUC18 (0.1 ng/μl), whereas competent cells with no DNA were used as a negative control. Finally, the plates were incubated overnight at 37°C.

2.13. Electroporation of E. coli DH5α

Electroporation of the E. coli DH5α was carried out if no E. coli JM109 transformants were obtained by heat shock transformation protocol. To prepare the electrocompetent E. coli DH5α, 2 × 750 ml TB medium in 2 liter baffled Erlenmeyer flasks were inoculated by cells of an overnight culture corresponding to 40 OD₆₀₀. The culture media were incubated overnight at room temperature until the OD₆₀₀ of 0.5 to 1.5 was reached. Next, the cell were placed on ice for 15 min and then centrifuged for 15 min at 4°C at 3000 rpm in a GS-3 rotor (SORVALL). Each pellet was washed with 150 ml sterile H₂O and subsequently resuspended in 2 × 18 ml (2 tubes) 10% sterile glycerol. The cell suspension was centrifuged in a SS34 rotor (SORVALL) and the supernatant was discarded in a way that 2 ml of the supernatant remained in each tube. The final cell suspension (2 × 2 ml) was divided into 50 μl aliquots and stored at -70.

Prior to electroporation, the competent cells and the ligated DNA or plasmid DNA were mixed in an electroporation cuvette and placed on ice. Then, the cuvette was subjected to an electrical field in a Bio-Rad Gene Pulser II generating 2.5 kV, 25 μF and 200 Ω. Upon electroporation, 1 ml LB medium was added to the electropermeabilized cells and the bacterial culture was incubated for 1 h at 37°C on a roller drum. Finally, the cells were plated on LB agar plates containing the relevant antibiotic (160).
2.14. Transformation of B. subtilis

Transformation of the Bacillus subtilis strains was performed employing their natural transformation ability (86, 206). A single colony of B. subtilis was inoculated into 5 ml broth I and incubated overnight at 37°C. Competent cells were obtained by the inoculation of 1 ml of the overnight culture in 20 ml of broth I. The bacterial culture was incubated at 37°C for approximately 6 h. At the OD$_{600}$ of 1 – 2, the bacterial culture was centrifuged for 5 min at 10,000 rpm in a SS34 rotor (SORVALL). The pellet was subsequently resuspended in SMS broth and glycerol was added to a final concentration of 10% to store the cells at -70°C. 8 ml of broth II was inoculated by 1 ml of cell suspension and further incubated for 85 min at 37°C. The desired plasmid was added to 1 ml of the latter bacterial culture and the culture incubated on a roller drum for 30 min at 37°C. The culture was finally centrifuged for 5 min at 4500 rpm (Megafuge) and the resuspended pellet was plated on LB agar plates with relevant antibiotic.

2.15. Electroporation of B. subtilis

The electroporation of the B. subtilis strains was carried out as described before (252). 5 ml of LB containing 0.5 M glucitol was inoculated by a single colony of B. subtilis and incubated overnight at 37°C. Subsequently, the overnight culture was diluted (1:16) by 75 ml of LB$_{\text{glucitol}}$ and incubated until an OD$_{600}$ of 0.85 – 0.95 was obtained. The cells were then centrifuged for 10 min at 4°C at 6500 rpm in a SS34 rotor (SORVALL) and the pellet was washed four times by ice-cooled EP buffer (1×10 ml and 3×5 ml). Finally, the cells were resuspended in 1 ml EP buffer to provide an OD$_{600}$ of 50 – 56 OD$_{600}$/ml. Aliquots of 60 µl of the cell suspension were frozen at -70°C. Electroporation was performed using 60 µl of competent cells with approx. 50 ng of plasmid in a cooled electroporation cuvette. The cell-DNA mixture was subjected to an electrical field in a Bio-Rad Gene Pulser II generating 2 kV, 25 µF and 200 Ω. Finally, recovery broth (1 ml) was added to the electropermeabilized cells and the bacterial culture incubated for 3 h at 37°C followed by plating on the LB agar supplemented by an antibiotic.
2.16. Protein analysis methods

2.16.1. Cell disruption

2.16.1.1. Cell disruption by sonication

Cell density of the *E. coli* culture was determined by a spectrophotometer at 600 nm wavelength (OD\textsubscript{600}) prior to disruption. Unless otherwise specified, 10 OD\textsubscript{600} of the bacterial culture was centrifuged for 5 min at 4500 rpm (Megafuge). After washing the pellet by the desired resuspension buffer, the pellet was dissolved in the same resuspension buffer. The cell suspension was cooled on ice-water and the sonication was performed with 50% “Duty cycle” for 3 × 30 sec with 30 sec pause in between. The soluble as well as the insoluble fractions of the bacterial lysate were separated by centrifugation for 10 – 15 min at 4°C at 14,000 rpm (Biofuge). The supernatant was transferred into a new ice-cooled Eppendorf tube and the pellet dissolved in 1 ml of the resuspension buffer. 12 μl of the soluble and insoluble fractions were used to analyze the expressed protein on SDS-PAGE.

2.16.1.2. Cell disruption by high pressure homogenizer

Gene expression in *B. subtilis/E. coli* was followed by cell disruption using a high pressure homogenizer (EmulsiFlex-C5) in order to purify the desired protein. First of all, 200 ml of bacterial culture was centrifuged for 5 min at 8,500 rpm in a GSA rotor (SORVALL) and the bacterial pellet was washed once in resuspension buffer. Afterwards, the bacterial pellet was dissolved in 20 ml of resuspension buffer and poured into the ice-cooled chamber of the high pressure homogenizer. The bacterial suspension was then subjected to approx. 10,000 to 15,000 kPa pressure and the cells were completely ruptured after 2 – 3 min. The bacterial lysate was then centrifuged in the Biofuge for 15 – 30 min at 13,000 rpm at 4°C to separate the soluble and insoluble fractions. The supernatant (cleared lysate) was transferred into a new ice-cooled Eppendorf tube, while the pellet was dissolved in 1 ml of the same resuspension buffer. Both supernatant and the pellet fractions were loaded onto a SDS-PAGE to analyze the protein content.
Materials and Methods

The cleared lysate was then used for the protein purification by affinity chromatography or ion-exchange chromatography.

2.16.2. SDS-PAGE

The bacterial proteins were separated by a discontinuous SDS polyacrylamide gel electrophoresis (SDS-PAGE) (120). The discontinuous system is based on a stacking gel (Tris-glycine buffer pH 6.8; 4% acrylamide) which is poured on top of a running gel (Tris-glycine pH buffer 8.8; 8 to 12% acrylamide). In this study, 8% and 12% SDS-PAGE gels were used. The following table shows the amount of ingredients for two gels:

<table>
<thead>
<tr>
<th>Components</th>
<th>Running gel (ml)</th>
<th>Stacking gel (ml)</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>8%</td>
<td>12%</td>

<td>6.6</td>
</tr>
</tbody>
</table>

In general, the length of the stacking gel was ¼ of the running gel. To separate the protein on SDS-PAGE, it was mixed with a 5x sample loading buffer followed by an incubation of the sample for 10 min at 98°C. After cooling, the denatured protein was loaded into the wells of gel and a current of 10 – 15 mA (per gel) applied. When the blue color of the sample passed the stacking gel, the current was increased to 20 mA (per gel). After electrophoresis, the gel was incubated for 30 – 60 min in Coomassie stain solution at room temperature. Then, the gel was covered by the destain solution to be destained by gentle agitation overnight.
2.16.3. Native PAGE electrophoresis

The native polyacrylamide gel electrophoresis (Native PAGE) was used to separate the intact proteins based on their charge to mass ratio. This method was used to study the binding of the regulatory proteins to their DNA binding sequence. For this purpose, the purified protein was mixed with the DNA (50 – 400 bp length) and the desired shift buffer. After the incubation, the mixture was loaded onto the 6% polyacrylamide gel. Preparation of two gels was performed according to the below table:

<table>
<thead>
<tr>
<th>Components</th>
<th>Amount (ml)</th>
</tr>
</thead>
<tbody>
<tr>
<td>30% acrylamide (37.5 acrylamide : 1 bisacrylamide)</td>

<tr>
<td>H2O</td>
<td>11.9</td>
</tr>
</tbody>
</table>

The samples were directly loaded on to the gel and the gel was run at 15 – 20 mA.

2.16.4. Bradford assay

Concentration of the total protein was measured according to the Bradford method (16). The sample was diluted up to 800 µl in ddH2O and 200 µl of Bio-Rad reagent, containing Coomassie Brilliant Blue G-250, phosphoric acid, and methanol, was added. The mixture was incubated for at least 15 min at room temperature. Next, the absorbance of the samples was measured at 595 nm in a spectrophotometer. As a blank sample, 800 µl water was mixed with 200 µl of Bio-Rad reagent. The standard curve was depicted by the measurements of various BSA concentrations between 0 – 1.38 mg/ml. Finally, the concentration of the protein was calculated by the following equation:

\[
\text{Protein conc. (mg/ml)} = \frac{(\text{Sample OD}_{595} - 0.6273)}{0.0514}
\]
2.16.5. Affinity chromatography by Ni-NTA agarose column

The cleared lysate of *B. subtilis* producing the His$_6$-tagged protein was prepared according to section 3.17.1.2. Two different buffers were used as listed in section 3.6 which were based on 50 mM sodium phosphate pH 8 and 50 mM HEPES pH 7.4. Purification of the His$_6$-tag protein was performed by the addition of 1 ml of 50% Ni-NTA slurry (Qiagen) to 4 ml cleared lysate obtained from cells of approximately 56.5 OD$_{600}$. PMSF was added to a final concentration of 2 mM and the mixture was gently shaked for 60 min at 4 °C. Next, the lysate-Ni-NTA mixture was loaded into a column with the bottom outlet cap. After dripping the flow-through, the column was washed twice with 4 ml wash buffer (20 mM imidazole). Finally, 500 µl elution buffer containing 250 mM imidazole was added four times to the column. 15 mM EDTA was added to the elution fraction in order to bind to the trace amount of the Ni$^{2+}$ washed from the column. The elution fractions were passed through a PD MidiTrap G-25 column to remove the imidazole. The whole procedure was performed at 4°C.

2.16.6. Buffer exchange by PD MidiTrap G-25 column

The buffer of the eluted His$_6$-tagged protein was exchanged for the resuspension buffer with the same components to remove the imidazole. Therefore, PD MidiTrap G-25 columns (GE Healthcare), containing Sephadex® G-25 medium, were used to perform the buffer exchange. The 500 µl of the elution fraction was diluted to 1 ml by resuspension buffer. Next, the 1 ml was loaded onto the column. After dripping of excess liquid, 1.5 ml of the resuspension buffer was used to elute the protein. The procedure was performed at 4°C. The final elution fraction was used for the electrophoretic mobility shift studies.

2.16.7. Ion-exchange chromatography (IEC)

Purification of the native protein (with no tag) was carried out in order to perform the electrophoretic mobility shift assay. In this method, separation is based on the protein electrical charge. There are two different IECs: anion exchange chromatography and cation exchange
chromatography. Depending on the pH of the buffer, proteins retain positive or negative charges. Therefore, cation exchange is used for separation of positively charged proteins by a negative surface, while anion exchange acts reverse. In this study, anion exchange chromatography was attended using Pharmacia Liquid Chromatography Controller LCC-500 Plus, Fraction collector FRAC-200, and a Mono Q® HR 5/5 column (Pharmacia). Start buffer (Buffer A) had low ionic strength, whereas high ionic eluent buffer (Buffer B) contained 1M NaCl. The parameters of the chromatography are listed below:

<table>
<thead>
<tr>
<th>Components</th>

2.16.8. Electrophoretic mobility shift

The electrophoretic mobility shift assay (EMSA) was performed to identify the specific binding site of the MtlR activator protein on the corresponding promoter sequences. To show this interaction, the $P_{mtlA}$ promoter region was amplified from plasmid pKAM1 using the specific forward oligonucleotide and a reverse Cy5-labeled oligonucleotide (s5959 or s5960). 200 fmol of the purified PCR product was then used in a 50 μl shift reaction. In addition, 25 μl of 2x shift buffer (or 10 μl of 5x shift buffer) was added to the reaction. Finally, different amounts of the purified protein were added to the reaction (table 2.5). After incubation of the reaction on ice for 15 – 30 min, 10 μl of the reaction was loaded on the 6% native gel. The gel was run at 20 V at room temperature. Ultimately, the gel was scanned by a phosphorimager to detect the Cy5-labelled samples. The DNA-Protein complex migrates slower than the DNA alone.

2.17. β-galactosidase assay (Miller’s assay)

Activity of β-galactosidase was measured according to Miller’s assay (151) in a colorimetric way by using ortho-nitrophenyl-β-galactoside (ONPG). The enzymatic reaction was performed by the addition of 100 µl of bacterial culture to 900 µl of Z buffer. Then, 10 µl toluene was added to the suspension and incubated on a roller drum for 30 min at 37 °C. Next, the mixture was subjected to air flow in order to evaporate the residual toluene. Finally, ONPG was added to the mixture and the reaction was stopped by 500 µl Na₂CO₃ (1 M). The OD₄₂₀ and OD₅₅₀ of the enzymatic reaction were measured and the corresponding Miller units (M.U.) are calculated by the following equation:

\[
\text{1 Miller Unit} = 1000 \times \frac{\text{OD}_{420} - (1.75 \times \text{OD}_{550})}{t \times v \times \text{OD}_{600}}
\]

where:
- t: reaction time in minute
- v: sample volume in milliliters (0.1 in here)
- OD₄₂₀: absorbance of yellow color which should be less than 0.65
- OD₅₅₀: scatter from cell debris
- 1.75 is the constant in order to approximate the scatter observed at 420 nm
- OD₆₀₀: bacterial culture turbidity at 600 nm wavelength

2.18. Fluorescence measurement

Fluorescence intensity of the recombinant eGFP was conducted by using a Spectrafluor microplate reader (Tecan Group Ltd) according to Wenzel et al. (242). At first, the bacterial culture was diluted to obtain an OD₆₀₀ of 0.3. Then, 100 µl of the diluted cells were transferred into 96-well microplates (Greiner-Bio One GmbH, Frickenhausen, Germany). As a blank sample,
100 μl of the same medium (uncultured) was applied. The measurements were performed using excitation filter at 485 nm, emission filter at 535 nm, gain [manual]: 60, 20 μs integration time, 3 flashes, top read. For each sample, the measurement was carried out in triplet. Finally, the average of the blank was subtracted from the average of the samples to get the final value.

2.19. Bioinformatic

Nucleotide alignment was performed using GENtle v.1.9.4 (University of Cologne, Germany). Clone manager basic version 8 (Sci-Ed software, USA) was used for cloning simulation and plasmid mapping. The genome sequence of *B. subtilis* 168 was firstly obtained from SubtiList World-Wide Web Server ([http://genolist.pasteur.fr/SubtiList/](http://genolist.pasteur.fr/SubtiList/)) (117, 155-157), while GenoList World-Wide Web Server was used after the update of the genome sequence of *B. subtilis* ([http://genodb.pasteur.fr/cgi-bin/WebObjects/GenoList.woa](http://genodb.pasteur.fr/cgi-bin/WebObjects/GenoList.woa)) (9).
3. Results

3.1. Activity of the mtlAFD promoter ($P_{mtlA}$)

In order to identify the promoter of the mtlAFD operon ($P_{mtlA}$), the region between the stop codon of $ycnL$, the upstream gene, and the start codon of $mtlA$ on the $B. subtilis$ 168 chromosomal DNA was amplified by oligonucleotides s5526 and s5527 in a PCR. The amplified fragment was then inserted upstream of the $lacZ$ reporter gene, into vector pSUN279.2 via NheI/AflII restriction sites and created pKAM1 (Fig. 3.2.A). By this means, the activity of $P_{mtlA}$ was represented by the $\beta$-galactosidase activity. Plasmid pSUN279.2 is a derivative of pMTLBS72, which is a $B. subtilis/E. coli$ shuttle vector, containing a pMB1 origin of replication originated from pUC18 for $E. coli$ and pBS72 origin of replication for $B. subtilis$. Replicon pBS72, which has been isolated from $B. subtilis$, is a stable theta replicating plasmid with low copy number in $B. subtilis$ (6 copies per chromosome). Afterwards, $B. subtilis$ 3NA was transformed with pKAM1. Strain 3NA pKAM1 was cultivated in LB and induced by 0.2% mannitol at the OD$_{600}$ of 0.4. The growth of the bacteria and the production of $\beta$-galactosidase were determined at intervals of 1 h.

![Fig. 3.1](image-url) **Fig. 3.1.** (A) $\beta$-galactosidase activity and growth curve of strain 3NA pKAM1 induced with 0.2% mannitol. (B) $\beta$-galactosidase activity and growth curve of the uninduced strain 3NA pKAM1 is shown. Mannitol was added at time 0 h.
As shown in Fig. 3.1.A, the maximal $\beta$-galactosidase activity was detected already 1 h after the addition of mannitol to the 3NA pKAM1 culture. This was likely due to the consumption of mannitol as a carbon source. In contrast, uninduced 3NA pKAM1 showed a low $\beta$-galactosidase activity (Fig. 3.1.B). Thereafter, $\beta$-galactosidase activity was determined 1 h after the addition of the sugars. Next, the influence of various sugars on the $P_{mtlA}$ activity in 3NA pKAM1 was investigated (Fig. 3.2.B). Mannitol and glucitol were added as the specific and non-specific inducers, respectively. To see the catabolite repression, glucose was added, while xylose, a non-PTS sugar, was a control. $\beta$-galactosidase activity was increased 27-fold by addition of mannitol. Moreover, no influence on $P_{mtlA}$ activity was observed by the addition of xylose alone or together with mannitol. In contrast, addition of the glucose repressed $P_{mtlA}$ by 2.7-fold. Likewise, addition of glucose to the bacterial culture reduced the basal activity in uninduced $P_{mtlA}$. Finally, glucitol, as a non-specific inducer, induced $P_{mtlA}$ by 10.6-fold. Similar to mannitol-induced $P_{mtlA}$, addition of glucose lowered the glucitol-induced $P_{mtlA}$ activity.

![Fig. 3.2](image)

**Fig. 3. 2.** (A) Upstream sequence of *mtlAFD* containing $P_{mtlA}$ fused to *lacZ* on pKAM1. The $P_{mtlA}$ region is located between *NheI* and *AflIII* restriction sites. The region between *AflIII* and *lacZ* start codon is originated from bacteriophage T7 gene 10 (49). The putative transcriptional terminator of *ycnL* is highlighted in gray. Ribosomal binding sites (RBS) of $P_{mtlA}$ (W) and pSUN279.2 (V) are underlined. The stop codon of *ycnL* and start codon of *lacZ* are shown by capital letter. The end of *ycnL* and start codon of *lacZ* genes are shown by dashed arrows (B) $\beta$-galactosidase activity of 3NA pKAM1 in the presence of different sugars. Strain 3NA pKAM1 was induced at the OD$_{600}$ of 0.4, and the $\beta$-galactosidase was measured after 1 h.
3.2. Identification of the $P_{mga}$ transcription start site

To determine the $P_{mga}$ core elements, it was necessary to identify the transcription start site of $P_{mga}$. To do so, primer extension method based on Cy5-labeled DNA was carried out. The Cy5-labeled oligonucleotides, s5959 and s5960, are reverse complementary of $lacZ$ starting at 89 bp and 51 bp downstream of the $lacZ$ start codon. At first, strain 3NA pKAM1 was cultivated in LB and induced by 0.8% mannitol, whereas uninduced 3NA pKAM1 was used as a control. Afterwards, total RNA of the cells was extracted 1 h after the addition of mannitol. Hybridization of the primer s5959 (or s5960) to mRNA and reverse transcription was carried out to generate the cDNA. In parallel, plasmid pKAM1 was sequenced with the same oligonucleotide in a dideoxy chain termination reaction method. Finally, the generated Cy5-labeled fragment band of cDNA was analysed in comparison to the fragment bands obtained in the sequencing reaction (Fig. 3.3.A). According to the primer extension experiment, the transcription starts at a C residue located 92 bp upstream of the $lacZ$ start codon and 72 bp upstream of the $mga$ start codon in the $mga$ operon (Fig. 3.3.B).

Fig. 3.3. (A) Primer extension of $P_{mga}$ on plasmid pKAM1. A, C, G, and T show the ddATP, ddCTP, ddGTP, and ddTTP used in the chain termination reaction. Total RNA of induced (+) and uninduced (-) 3NA pKAM1 were used for reverse transcription reaction. The transcription start site is shown by an asterisk. (B) Transcription start site of $P_{mga}$ is shown by bold capital letter. $P_{mga}$ core elements, namely -10 box and -35 box are enclosed by rectangles. An incomplete inverted repeat sequence is shown by the arrows and dashed lines located upstream of the -35 box. Putative catabolite responsive element ($cre$) is underlined by a dash.

![Diagram](image.png)
Results

The determination of the transcription start site allowed the identification of the -10 and -35 conserved boxes of $P_{m2A}$. The -10 box had the sequence TAACAT (consensus: TATAAT) and -35 box the sequence TTGTAT (consensus: TTGACA), respectively (mismatches to the consensus sequence are underlined). Moreover, a catabolite responsive element (cre) which had an overlap with the -10 box was found. The sequence of the cre box (CTGTAAGCGTTTTAA) showed two mismatches (underlined) compared to the cre consensus sequence (WTGNAARCGNWWWCA). Finally, an incomplete inverted repeat was detected upstream of the -35 box (TTGTCACAGTCATGTGCCAA) which could be the activator binding site (Fig. 3.3.B).

3.3. Shortening of the $P_{m2A}$ sequence

Identification of the transcription start site of $P_{m2A}$ revealed the $P_{m2A}$ core elements as well as the probable regulatory sequences. However, the complete length of the amplified $P_{m2A}$ sequence on pKAM1 was 181 bp. It contained the terminator and stop codon of ycnL as well as the ribosomal binding site of $P_{m2A}$ (Fig. 3.3.B). Hence, the 181 bp sequence was shortened in order to identify the essential parts of the $P_{m2A}$ sequence (Fig. 3.4.A).

![Diagram](image1.png)

**Fig. 3. 4.** (A) The sequence of $P_{m2A}$ and the constructs thereof. The boundaries of the constructs are indicated by an arrow and a rectangle. The red sequence of pKAM1 was deleted to create pKAM9. The blue sequence in pKAM9 was deleted to construct pKAM12. (B) β-galactosidase activity of strain 3NA harboring pKAM1 and shortened $P_{m2A}$ constructs on pKAM9 and pKAM12.
In the first step, 20 bp of the 5’-end of the \( P_{mtlA} \) sequence including the terminator of \( ycnL \) was removed. The PCR was performed using oligonucleotides \( s6209/s5527 \) and \( B. subtilis \) 168 chromosomal DNA as the template. The PCR fragment was then digested by \( NheI/AflII \) and inserted into pSUN279.2. Plasmid pKAM9 was created by the insertion of shortened \( P_{mtlA} \) (Figure 3.4.A). After induction of strain 3NA pKAM9, it was observed that inducibility and maximal activity of \( P_{mtlA} \) remained intact (Fig. 3.4.B). Next, the wild type ribosomal binding site, RBS (W), was removed from pKAM9 through a PCR using oligonucleotides \( s6209 \) and \( s6213 \). Digestion of the PCR product and insertion into pSUN279.2 resulted in pKAM12. Surprisingly, mannitol-induced strain 3NA pKAM12 showed a considerably higher \( \beta \)-galactosidase activity than strain 3NA pKAM9 (Fig. 3.4.B). Plasmid pKAM12 was used for further investigations.

3.4. \( P_{mtlA} \) activity in minimal and rich medium

Prior to further investigation of \( P_{mtlA} \), the \( \beta \)-galactosidase activity of 3NA pKAM12 in minimal and rich media were compared. Spizizen’s minimal salt (SMS) and LB were chosen. SMS was supplemented by 1% glycerol as the main carbon source. Glucose (0.2%) and mannitol (0.2%) in combination or alone were added to the bacterial culture at the OD\(_{600}\) of 0.4. The samples were collected 1 h after the addition of sugars to measure the \( \beta \)-galactosidase activity. The results indicated that the \( P_{mtlA} \) activity was less inducible in LB compared to SMS caused by a higher basal activity, although the \( P_{mtlA} \) activity was almost doubled in LB. Regardless of the inducibility and maximal activity, glucose repression ratio (mannitol/mannitol + glucose) was almost the same in both media (Fig. 3.5). Thus, all of the further measurements were performed in LB medium due to the higher activity of \( P_{mtlA} \) as well as shorter lag phase of the growth of 3NA pKAM12.
3.5. Activity of the *mtlR* promoter (*P_{mtlR}*)

Regulation of the *mtlAFD* operon is controlled by an activator (MtlR) located 14.4 kbp downstream of the operon. Next, it was tested whether *P_{mtlR}* was regulated in the same way as *P_{mtlA}*. To investigate the regulation of the promoter of *mtlR* (*P_{mtlR}*), the upstream region of *mtlR* between *ycsN* stop codon and the *mtlR* start codon was amplified from *B. subtilis* 168 genome by oligonucleotides s5799 and s5800 (Fig. 3.6.A). Similar to *P_{mtlA}*, the promoter fragment was inserted into pSUN279.2 via *NheI/AflII* restriction sites creating pKAM3. Then, *B. subtilis* 3NA was transformed and the selected transformant, 3NA pKAM3, induced by different sugars. As shown in Fig. 3.6.B, *P_{mtlR}* was highly inducible by mannitol and glucitol similar to *P_{mtlA}*. The β-galactosidase activity of 3NA pKAM3, however, was drastically lower than of 3NA pKAM1 (172 Miller units compared to about 1,000 Miller units). Besides, glucose lowered the *P_{mtlR}* activity in the presence of either mannitol or glucitol. All together, the results indicated that *P_{mtlR}* is an autoinducible promoter with a 10-fold lower activity than *P_{mtlA}*. 

![Graph showing β-galactosidase activity of strain 3NA pKAM12 in LB compared to Spizizen’s minimal salt (SMS) with or without 0.2% mannitol, as well as with 0.2% mannitol + 0.2% glucose.](image)
Results

A

B

Fig. 3.6. (A) The upstream region of mtlR is depicted between NheI and AluII restriction sites. The stop codon of ycsN and start codon of lacZ are shown by capital letter. The end of ycsN is underlined by a dashed arrow. Ribosomal binding sites (RBS) of PmtlR (W) and pSUN79.2 (V) are underlined. (B) β-galactosidase activity of 3NA pKAM3 in the presence of mannitol, glucose, glucitol and xylose was monitored. The 3NA pKAM3 strain was induced at the OD₆₀₀ of 0.4 and the β-galactosidase activity was measured after 1 h.

3.6. Identification of the PmtlR transcription start site

The transcription start site of PmtlR was identified by primer extension method. A 3NA strain with plasmid pKAM3 harboring the intact promoter region of PmtlR was used as the source of mRNA. The total RNA of induced and uninduced 3NA pKAM3 were extracted and used for the reverse transcription with Cy5-labeled primer s5959 (or s5960). The obtained Cy5-labeled cDNA fragment was compared to the profile of the DNA sequencing reaction obtained from pKAM3 with the same primer. In this way, a single G residue was identified as the transcription start site of PmtlR (Fig. 3.7.A). The transcription start site was located 77 bp upstream of the mtlR start codon. Also, TATAAT and TTGATT boxes were determined as Pribnow box and -35 box, respectively (Fig. 3.7.B). Additionally, a cre site was located at the spacer sequence overlapping the -10 box. The cre sequence of PmtlR (TTGAAAGCGGTATT) showed a 2 bp mismatch (underlined) with the consensus cre sequence (WTGNAARGNNWCA). Ultimately, an incomplete inverted repeat upstream of the -35 box was found with similarity to the corresponding sequence detected in PmtlA.
Results

Fig. 3. 7. (A) Primer extension of *P*_{mtlR} on plasmid pKAM3. A, C, G, and T represent the ddATP, ddCTP, ddGTP, and ddTTP used for the chain termination reactions of the promoter sequencing. The cDNA band from the mRNA isolated from the induced and uninduced cultures are respectively shown in + and – lanes. (B) The sequence of *P*_{mtlR} on pKAM3 is shown. Transcription start site is indicated by bold capital letter. The -35 and -10 boxes are enclosed by rectangles. The cre site is underlined by a dash and the incomplete inverted repeat sequence is depicted by dashes and arrows. The end of ycsN and start of lacZ are depicted by dashed arrows.

3.7. Shortening of the 5’ untranslated region of *P*_{mtlR}-lacZ mRNA

The shortening of the *P*_{mtlA} 3’-end resulted in a higher *P*_{mtlA} activity (section 3.3). Therefore, the *P*_{mtlR} sequence was also shortened at its 3’-end. In the first step, the Shine-Dalgarno sequence of *P*_{mtlR} was removed in order to test whether the presence of two ribosomal binding sites decreased the β-galactosidase activity. The 3’-end shortened *P*_{mtlR} was amplified by a PCR using oligonucleotides s5799/s6392 and *B. subtilis* 168 chromosomal DNA. Plasmid pKAM18 was constructed by the insertion of the resulting fragment into pSUN279.2 via NheI/AflII (Fig. 3.8.A). Induction of strain 3NA pKAM18 indicated that the β-galactosidase activity in 3NA pKAM18 (having a single ribosomal binding site on *P*_{mtlA-lacZ} sequence) was half of 3NA pKAM3 (having two ribosomal binding site in *P*_{mtlR-lacZ} fusion) (Fig. 3.8.B). Previously, the shortening of the mRNA 5’ UTR of *P*_{mtlA-lacZ} to 61 bp improved the transcription/translation. Hence, the length of the mRNA leader region of *P*_{mtlR-lacZ}, *i.e.* the region between the transcription start site and start codon of lacZ, was shortened to 51 and 61 bp. Constructs pKAM86 with 61 bp and pKAM87 with 51 bp 5’ UTR were made in a PCR from *B. subtilis* 168.
Results

genome using s5799/s7066 and s5799/s7067 oligonucleotides, respectively. Unlike $P_{\text{mtlA}}$, induction of 3NA pKAM86 and 3NA pKAM87 resulted in a low activity compared to 3NA pKAM3 and the loss of induction. Taken together, shortening of the mRNA leader region of $P_{\text{mtlR}}$-$\text{lacZ}$ decreased the $\beta$-galactosidase activity. Nevertheless, pKAM18 having a single ribosomal binding site was used for further studies.

Fig. 3.8. (A) The sequence of $P_{\text{mtlR}}$ on pKAM3 and the truncated versions thereof. The first base pair of each shortened construct is enclosed by a rectangle and an arrow. The dashed rectangle shows the region deleted in pKAM18. The gray highlighted nucleotides are deleted in pKAM86. The deleted nucleotides in pKAM87 are shown by bold letters. (B) $\beta$-galactosidase activity of strain 3NA harboring pKAM3, pKAM18, pKAM86, and pKAM87 in the presence and absence of 0.2% mannitol for 1 h is shown.

3.8. Comparison of $P_{\text{mtlA}}$ and $P_{\text{mtlR}}$

To compare $P_{\text{mtlA}}$ and $P_{\text{mtlR}}$ without having the influence of different 5’ UTR, $P_{\text{mtlR}}$ was fused exactly at position +1 to the 5’ UTR of $\text{mtlA}$ on pKAM12. Oligonucleotides s5799/s7149 and s7150/s6213 were used to amplify the primary fragments, i.e. $P_{\text{mtlR}}$ and UTR$_{\text{mtlA}}$, by PCR from $B$. subtilis genomic DNA. Fusion PCR was performed using the primary PCRs products and oligonucleotides s5799/s6213. The final fragment was then inserted into pSUN279.1 via $\text{NheI}$ and $\text{AflIII}$ restriction sites (Fig. 3.9.A).
Transformation of *E. coli* JM109 by the ligation reaction showed no transformants. Therefore, *B. subtilis* 3NA was directly transformed with the ligation reaction and resulted in pKAM96. The β-galactosidase activity of induced and uninduced 3NA pKAM96 was compared to 3NA pKAM12 (P<sub>mtlA</sub>) and 3NA pKAM18 (P<sub>mtlR</sub>). In comparison with 3NA pKAM18, changing the 5’ UTR of *mtlR* by its counterpart from *mtlA* dramatically boosted the activity of P<sub>mtlR</sub>; however, P<sub>mtlR</sub> still showed a weaker activity than P<sub>mtlA</sub> (Fig. 3.9.B). Additionally, the basal activity of the P<sub>mtlR</sub>−UTR<sub>mtlA</sub> was 4.5-fold higher than P<sub>mtlA</sub>−UTR<sub>mtlA</sub>. This result indicated that the P<sub>mtlA</sub> is stronger than P<sub>mtlR</sub> as well as more tightly regulated.

### 3.9. HPr(H15−P)-dependent activity of P<sub>mtlA</sub>

Principally, PRD-containing activators and antiterminators are phosphorylated by HPr(H15−P) in the presence of their sugar inducer. Supposing that MtlR is phosphorylated by HPr, the activity of P<sub>mtlA</sub> was studied in *B. subtilis* strain TQ432, where the phosphoryl carrier histidine 15 of HPr was replaced with an alanine (mutant *ptsH*-H15A). Transformation of strain TQ432 by pKAM12 was performed in the minimal medium harboring glucitol instead of glucose as carbon source. In fact, TQ432 cannot grow on any PTS sugar due to the mutation of HPr-H15. Very low β-galactosidase activity was measured in the mannitol-induced and uninduced cultures.
Induction of $P_{mtlA}$ in TQ432 pKAM12 by mannitol in LB showed that the $P_{mtlA}$ activity was nearly abolished (Fig. 3.10).

![Fig. 3.10](image)

**Fig. 3.10.** β-galactosidase activity of strains 3NA (wild type) and TQ432 (ptsH-H15A) harboring pKAM12 is shown. The sugars were added at OD$_{600}$ of 0.4 and the β-galactosidase activity was measured after 1 h.

Besides, the presence of glucose had no effect on the $P_{mtlA}$ activity in the mutant. This indicated that HPr-H15 plays an essential role in the activation of MtlR demonstrating that MtlR is a PRD-containing activator, which is likely regulated by other mannitol PTS components. Therefore the effect of other $mtl$ components on $P_{mtlA}$ activity was investigated.

### 3.10. Deletion of the mannitol utilization genes in *B. subtilis*

#### 3.10.1. Deletion of the activator encoding gene (mtlR)

The regulatory effect of MtlR on $P_{mtlA}$ activity was investigated by the deletion of $mtlR$ within the chromosome of *B. subtilis* 3NA. Plasmid pSUN308.3 (see appendices) was used for construction of integration vectors in this study. Three antibiotic resistance genes reside on this plasmid including erythromycin located inside the deletion cassette for *B. subtilis*, spectinomycin for selection of single cross-over mutants of *B. subtilis*, and finally ampicillin for selection of the plasmid inside the *E. coli*. Amplification of the downstream flanking gene, *ydaB*, was performed by oligonucleotides s5860 and s5812 in a PCR from *B. subtilis* 168 genomic DNA and the PCR...
Results

product was inserted into plasmid pSUN308.3 via SpeI/StuI restriction sites (pKAM05). Then, upstream gene of mtlR, namely ycsN, was amplified in a PCR from B. subtilis 168 chromosomal DNA by oligonucleotides s5809 and s5810. The PCR fragment was digested by EcoRV and BglII and inserted into plasmid pKAM05. The resulting plasmid (pKAM4) harboring the cassette 'ycsN-ermC-ydaB' was linearized by PacI and used for integration into the genome of B. subtilis 3NA. The transformants were selected on LB medium supplemented by erythromycin. In order to confirm the double cross-over, the transformants were streaked on LB_Spec plates. Also, the deletion of mtlR was confirmed by PCR using oligonucleotides s5809/s5812 and the chromosomal DNA of the ΔmtlR mutant (Fig. 3.11.A). The ΔmtlR mutant (KM15) was unable to grow in mannitol minimal medium (Fig. 3.19). Subsequently, strain KM15 was transformed with pKAM12 and pKAM18 in order to study the effect of the MtlR on the P_{mtlA} and P_{mtlR} promoters. Deletion of the mtlR reduced the β-galactosidase activity of strain KM15 pKAM12 to 92 Miller units in the presence of mannitol. The same activity was observed in the absence of mannitol. This means that KM15 pKAM12 was no longer inducible by mannitol (Fig. 3.11.B). However, the presence of glucose still repressed the P_{mtlA} activity. Furthermore, β-galactosidase activity of KM15 pKAM18 was also declined. Besides, P_{mtlR} was no longer inducible in the ΔmtlR mutant (Fig. 3.12). This shows that MtlR regulates its own promoter. Similar to P_{mtlA}, P_{mtlR} activity was also repressed by glucose.

3.10.2. Deletion of the mannitol-specific enzyme II encoding genes (mtlAF)

The effect of the mannitol-specific enzyme II, i.e. EIICB^{Mt}l and EIIA^{Mt}l, on the P_{mtlA} and P_{mtlR} activities was studied by deletion of the mtlAF genes. The deletion cassette was constructed by the fusion of P_{mtlA} to mtlD. PCRs from the genome of B. subtilis 168 were performed using oligonucleotides s5918/s5919 and s5920/s5921. Final fusion PCR was accomplished by using oligonucleotides s5918/s5921 and the primary PCRs products. The P_{mtlA-mltD} fragment was subsequently digested by BglII/EcoRV and inserted into pSUN308.3 and created pKAM08. The upstream gene of mtlAFD operon, ycnL, was amplified in a PCR from B. subtilis 168 chromosome using oligonucleotides s6076 and s6079. The amplified ycnL was then digested by StuI/SpeI and inserted into pKAM08 to construct plasmid pKAM5.
Fig. 3.11. (A) The mannitol utilization genes and the mutations obtained by plasmids pKAM4 (ΔmtlR), pKAM5 (ΔmtlAF), pKAM6 (ΔmtlAFD), and pKAM14 (mtlD::ermC). (B) β-galactosidase activity of the strains KM12 (ΔmtlAF), KM13 (ΔmtlAFD), KM15 (ΔmtlR), and KM37 (mtlD::ermC) harboring pKAM12 is shown.
The strain 3NA was transformed with the deletion cassette ‘ycnl-ermC-P_{mtlA}-mtlD’ (pKAM5) and the transformants were selected on LB_{erm} (Strain KM12; Fig. 3.11.A). Confirmation of the deletion of mtlAF was performed by PCR using oligonucleotides s6067/s5921 and the chromosomal DNA of ΔmtlAF mutant. The strain was not able to grow on spectinomycin as expected for a double crossover event. Transformation of the strain KM12 (ΔmtlAF::ermC) by pKAM12 and pKAM18 was carried out. The transformants were then used for induction studies and their β-galactosidase activities were measured (Fig. 3.11.B and Fig. 3.12). Both of the promoters, P_{mtlA} and P_{mtlR}, were constitutively active in strain KM12 showing approximately 13,900 and 243 Miller units β-galactosidase activity, respectively. In other words, the presence of mannitol as the inducer had no influence on the P_{mtlA} or P_{mtlR} activity. In contrast, the presence of glucose repressed the P_{mtlA} and P_{mtlR} activities as shown in Fig. 3.11.B and Fig. 3.12. This shows that the P_{mtlA} and P_{mtlR} activities were inhibited by the mannitol-specific EII if mannitol was absent in the medium. By deletion of the transporter, this inhibitory effect was removed and the P_{mtlA} and P_{mtlR} were constitutively active.

**Fig. 3. 12.** P_{mtlR} activity in mannitol utilization deficient mutants. β-galactosidase activity of *B. subtilis* 3NA (wild type) and mannitol utilization deficient mutants, KM12 (ΔmtlAF), KM15 (ΔmtlR), and KM37 (mtlD::ermC), harboring pKAM18 (P_{mtlA}) is represented.
3.10.3. Deletion of \textit{mtlF} by a new markerless deletion system

In mannitol PTS, the separated cytoplasmic domain of the enzyme II complex, namely EIIA\textsuperscript{Mtl}, transfers the phosphate from HPr(H15~P) to the membrane anchored domains EIICB\textsuperscript{Mtl}. Therefore, the \textit{mtlF} gene (encoding the phosphocarrier protein EIIA\textsuperscript{Mtl}) was deleted within the chromosome of \textit{B. subtilis} 3NA by a new markerless deletion system based on the site-specific recombination. A specific recombination sequence was designed according to a \textit{mrpS} site (238) and a \textit{loxP} site (95). The \textit{mrpS} site is recognized by a tyrosine recombinase (MrpA) found in \textit{Streptomyces coelicolor} A3(2), while \textit{loxP} is recognized by the bacteriophage P1 recombinase Cre. The \textit{mrpS} site contains a 30 bp inverted repeat sequence separated by a 6 bp spacer. Likewise, \textit{loxP} contains a 26 bp inverted repeat sequence separated by a 8 bp spacer. In a recently designed sequence, half of the inverted repeat sequence of \textit{mrpS} was replaced with the \textit{loxP} in a way that the new sequence, denoted \textit{mroxP}, was recognized by the Cre recombinase (Warth \textit{et al.}, unpublished). The recombination between the two \textit{mroxP} sequences by Cre recombinase resulted in the deletion of the desired gene located between the \textit{mroxP} sites. Interestingly, a new recombination sequence was constructed by the recombined sequence which can be recognized by MrpA (Warth \textit{et al.}, unpublished; Fig. 3.13). This deletion system was employed for a markerless deletion in \textit{B. subtilis}. The deletion vector was constructed using pIC20HE as the parental vector (1). Two long oligonucleotides s6465/s6466 harboring the \textit{mroxP} were used to amplify the chloramphenicol acetyl transferase of plasmid pMW363.1 originated from \textit{Streptococcus pneumoniae}. Plasmid pMW363.1 is a derivative of pSUN308.3 harboring chloramphenicol resistance gene. The resulting fragment, \textit{mroxP-cat-mroxP} was then inserted into pIC20HE via \textit{XhoI} and \textit{EcoRI} restriction sites (plasmid pKAM19; Fig. 3.14.A). Afterwards, deletion of the \textit{mtlF} was performed using the 5’-truncated \textit{mtlA} as the upstream flanking and the \textit{mtlD} as the downstream flanking sequence of \textit{cat} gene. Oligonucleotides s6759 and s6760 were used to amplify the truncated \textit{mtlA} from \textit{B. subtilis} 168 chromosome in a PCR. The PCR fragment was then inserted via \textit{BamHI/XhoI} restriction sites into pKAM19 to create pKAM020. In another PCR, the truncated \textit{mtlD} sequence was amplified by PCR from genomic DNA of \textit{B. subtilis} 168 using oligonucleotides s6761/s6762. The amplified \textit{mtlD} was inserted into the pKAM020 via \textit{NheI/SacI} and constructed pKAM47.
Fig. 3. 13. The mrps recombination site recognized by MrpA site-specific recombinase of *Streptomyces coelicolor* A3(2) and *loxP* recognized by Cre site-specific recombinase of bacteriophage P1 are depicted. The constructed sequence *mroxP* is a combination of *mrps* and *loxP* sequences which is recognized by Cre recombinase. After recombination, the final emerged sequence is only recognized by MrpA.

To integrate plasmid pKAM47 into the chromosome of *B. subtilis* 3NA, pKAM47 DNA was digested by *Sca*I followed by the natural transformation of the strain 3NA. The transformants were then selected on LB<sub>cm</sub> and the integration of the DNA fragment was controlled by PCR. Next, the Δ<sub>mtlF::mroxP-cat-mroxP</sub> strain was transformed with an unstable plasmid, namely pJOE6732.1 (see appendices). Plasmid pJOE6732.1, a derivative of pAMβ1 plasmid, contains the *P<sub>xyl</sub>-cre<sub>P1</sub>* expressing the Cre recombinase. After selection of the transformants on LB<sub>spc</sub>, one of the transformants was cultivated at 37°C for 24 h. During the incubation, the Cre recombinase was expressed and recombined the *mroxP* sequences and resulted in the deletion of the *cat* gene from the Δ<sub>mtlF::mroxP-cat-mroxP</sub> cassette. In addition, the bacteria lost pJOE6732.1 due to its instability. After 24 h incubation, dilutions of the bacterial culture were plated on LB agar and the
transformants were checked for the loss of chloramphenicol and spectinomycin resistance. The mtlf deficient strain, called KM103, was unable to grow on mannitol minimal medium. Also, strain KM103 was sensitive to chloramphenicol and spectinomycin (Fig. 3.14.B).

**Fig. 3. 14.** (A) Plasmid map of the plasmid pKAM19 used as the backbone for the markerless deletion of mtlf. (B) Deletion of the mtlf using mroxP recombination sites. In the first step, plasmid pKAM47 harboring the deletion cassette was integrated into the chromosome of B. subtilis 3NA. Afterwards, the expression of the Cre recombinase led to the site-specific recombination at the mroxP sites. The markerless Δmtlf strain KM103 was constructed by the deletion of the cat gene from the chromosome.

Finally, β-galactosidase activity of KM103 pKAM12 was measured in the presence of mannitol and glucose (Fig. 3.11.B.). Similar to KM12 pKAM12, the \( P_{mtlA} \) activity in KM103 pKAM12 was constitutive, but the strain grew slower than the wild type. Unlike the KM12 pKAM12, β-galactosidase activity surprisingly boosted up to 24,800 Miller units in KM103 pKAM12. This was almost double of the activity of the induced \( P_{mtlA} \) in the wild type strain. As expected, the addition of glucose reduced the β-galactosidase activity to 8,100 Miller units. Altogether, deletion of the EIIA\(^{Mtl}\) removed the \( P_{mtlA} \) inhibition in the absence of mannitol; however, the reason for the high activity of the \( P_{mtlA} \) is still unknown.
3.10.4. Disruption of the mannitol 1-phosphate dehydrogenase encoding gene (mtlD)

The effect of the mannitol 1-phosphate dehydrogenase on the $P_{mtlA}$ and $P_{mtlR}$ activities was investigated by the disruption of mtlD. To construct the integration cassette, a truncated version of mtlD was amplified in a PCR from B. subtilis 168 chromosome using oligonucleotides s6344/s6345. The resulting fragment was then inserted into pSUN308.3 via EcoRV/NdeI restriction sites (pKAM015). Afterwards, the erythromycin gene $ermC$ was amplified by PCR from pSUN308.3 by oligonucleotides s5069/s5070. The blunt ends PCR product was then inserted into pKAM015 via HincII restriction site inside the mtlD (plasmid pKAM14). Integration of the cassette ‘mtlD-ermC-mtlD’ into the chromosome of B. subtilis 3NA was performed and the transformants were selected on LB$_{erm}$. The disruption of mtlD was confirmed by PCR using oligonucleotides s6344 and s6345. The mtlD::ermC mutant (strain KM37) was cultivated in LB supplemented by 1% glucose (as control), mannitol or glucitol. Incubation of the cell culture at 37°C revealed that the mannitol and glucitol retarded the growth of the cells in comparison to glucose (Fig. 3.15.A). In other words, the mannitol and glucitol are partially toxic for the cells and the cells were swollen and lysed after 4 h of incubation (Fig. 3.15.B).

![Fig. 3.15](image)

**Fig. 3.15.** (A) Growth curve of the strain mtlD::ermC (strain KM37) in LB harboring 1% glucose, mannitol or glucitol as the main carbon source. (B) The swollen cells of B. subtilis KM37 in LB harboring mannitol as the main carbon source.
Likewise, the influence of the disruption of mannitol 1-phosphate dehydrogenase on the activity of $P_{mtlA}$ was investigated. Strain KM37 pKAM12 was induced by different sugars (Fig. 3.11.B). Unexpectedly, the basal $\beta$-galactosidase activity of the KM37 pKAM12 was higher than the 3NA pKAM12 (4.7-fold). Due to the high basal $\beta$-galactosidase activity, the inducibility of the cells by mannitol were reduced. Besides, the presence of mannitol and glucitol resulted in partial lysis of the cells after 1 h. In contrast, addition of glucose prevented the lysis of the bacteria, although the $P_{mtlA}$ activity was also repressed. In addition to pKAM12 harboring $P_{mtlA}$, KM37 was transformed with pKAM18 to monitor the $P_{mtlR}$ activity in $mtlD::ermC$ mutant. The results showed that the $\beta$-galactosidase activity of KM37 pKAM18 was higher than of 3NA pKAM18 in the presence and absence of mannitol (Fig. 3.12). Nonetheless, the catabolite repression remained effective. Overall, $P_{mtlA}$ and $P_{mtlR}$ were inducible in KM37, while glucose repressed their activities.

3.10.5. Deletion of the $mtlAFD$ operon

The whole operon of the mannitol PTS, $mtlAFD$, was replaced with erythromycin resistance gene in order to investigate the $P_{mtlA}$ activity in the absence of the EII$^{Ml}$ components as well as mannitol 1-phosphate dehydrogenase. Construction of the $mtlAFD$ deletion cassette was carried out by amplification of $ycsA$ in the first step. The $ycsA$ gene was amplified by PCR from $B. subtilis$ 168 chromosome using oligonucleotides s5994/s5995. The amplified fragment was then inserted into pSUN308.3 by SpeI/StuI restriction sites (pKAM011). Next, oligonucleotides s6068 and s6080 were used for a PCR from genomic DNA of $B. subtilis$ 168 to amplify $ycnL$. By insertion of the $ycnL$ into pKAM011 via EcoRV/BglII restriction sites, plasmid pKAM6 was constructed. Afterwards, the strain 3NA was transformed with pKAM6 and the erythromycin resistant transformants were selected (strain KM13). Subsequently, transformation of KM13 by pKAM12 was performed and the transformants were selected on spectinomycin. Induction of KM13 pKAM12 revealed an unexpected reduction in the $\beta$-galactosidase activity by 13-fold to about 1,000 Miller units compared to 3NA pKAM12. Nevertheless, $P_{mtlA}$ in $\Delta mtlAFD$ showed constitutive activity similar to $mtlAF$ and $mtlF$ mutants. Also, the catabolite repression was functional reducing the $\beta$-galactosidase activity to 200 Miller units (Fig. 3.11.B).
3.11. Regulation of $P_{mtlA}$ and $P_{mtlK}$ by glucitol

3.11.1. $P_{mtlA}$ induction by glucitol

Glucitol is a sugar alcohol which is taken up by a non-PTS system in *B. subtilis*. Induction of the mannitol PTS by glucitol was reported before (239). To study the induction of $P_{mtlA}$ by glucitol, wild type strain 3NA as well as KM12, KM13, KM15, KM37 and KM103 harboring pKAM12 (containing $P_{mtlA}$-$lacZ$) were induced by glucitol (Fig 3.16). Induction of 3NA pKAM12 by glucitol gave about 8,000 Miller units β-galactosidase activity in comparison to the uninduced strain showing only 600 Miller units β-galactosidase activity. Besides, addition of glucose reduced the β-galactosidase activity by 1.7-fold. Deletion of $mtlR$ lowered the β-galactosidase activity of KM15 pKAM12 in LB with glucitol to 81 Miller units and 100 Miller units without glucitol. In other words, $P_{mtlA}$ was no longer inducible in KM15 pKAM12 and the $P_{mtlA}$ activity was depleted. Likewise, the addition of glucose to KM15 pKAM12 culture decreased β-galactosidase activity to 61 Miller units. Moreover, deletion of $mtlAF$ rendered $P_{mtlA}$ constitutive in the presence and absence of glucitol. Besides, the presence of glucose reduced the β-galactosidase activity of KM12 pKAM12. This was similar to previous attempts where the influence of mannitol on $P_{mtlA}$ in KM12 pKAM12 was investigated (section 3.10.2). Deletion of $mtlF$ boosted the β-galactosidase activity to 18,000 – 25,000 Miller units. Also, $P_{mtlA}$ was constitutive in KM103 pKAM12. Surprisingly, glucitol-induced KM37 pKAM12 culture expressed 11,800 Miller units β-galactosidase activity which was almost identical to mannitol-induced KM37 pKAM12. Indeed, the presence of mannitol 1-phosphate dehydrogenase in the cell made a significant difference between mannitol and glucitol as the inducers. Finally, deletion of the $mtlAFD$ operon led to reduction of the $P_{mtlA}$ constitutive activity. The β-galactosidase activity of KM13 pKAM12 in LB was about 1,000 Miller units in the presence and absence of glucitol which was the same as with KM13 pKAM12 in LB with or without mannitol.
Results

3.11.2. Induction of $P_{mtlR}$ by glucitol

The activity of $P_{mtlR}$ was investigated in the presence of glucitol in $B. subtilis$ 3NA (wild type) as well as in mannitol utilization deficient mutants. For this purpose, $B. subtilis$ 3NA, KM12 ($\Delta mtlAF$), KM13 ($\Delta mtlAFD$), KM15 ($\Delta mtlR$), KM37 ($\Delta mtlD$), KM103 ($\Delta mtlF$) harboring pKAM18 ($P_{mtlR}$) is demonstrated. Glucitol (0.2%) and glucose (0.2%) were added at the OD$_{600}$ of 0.4 and the $\beta$-galactosidase activity was measured after 1 h.

The activity of $P_{mtlR}$ was investigated in the presence of glucitol in $B. subtilis$ 3NA (wild type) as well as in mannitol utilization deficient mutants. For this purpose, $B. subtilis$ 3NA, KM12 ($\Delta mtlAF$), KM15 ($\Delta mtlR$), and KM37 ($mtlD::ermC$) containing pKAM18 were induced by glucitol (Fig. 3.17). The $\beta$-galactosidase activity of the strains was measured 1 h after the addition of glucitol. Glucose was simultaneously added to the bacterial culture to test the carbon catabolite repression effect. The results showed that $P_{mtlR}$ was less inducible by glucitol than mannitol in the 3NA pKAM18 strain with about 51 Miller units $\beta$-galactosidase activity. Additionally, presence of glucose repressed the $P_{mtlR}$ activity in 3NA pKAM18. Deletion of the activator, MtlR, decreased the $\beta$-galactosidase activity to 10 – 16 Miller units in KM15 pKAM18. In this case, $P_{mtlR}$ was no more inducible by glucitol. The presence and absence of glucitol had no influence on the $\beta$-galactosidase activity in KM12 pKAM18 where $P_{mtlR}$ was constitutive. However, the addition of glucose decreased the $\beta$-galactosidase activity in KM12 pKAM18. Finally, $\beta$-galactosidase activity of KM37 pKAM18 in LB with or without glucitol was identical to KM37 pKAM18 with or without mannitol.
Results

Fig. 3. 17. Induction of \( P_{mtlR} \) by glucitol in strain 3NA and the mannitol utilization deficient mutants. \( \beta \)-galactosidase activity of \( B. \ subtilis \) 3NA, KM12 (\( \Delta \)mtlAF), KM15 (\( \Delta \)mtlR), and KM37 (\( \Delta \)mtlD) harboring pKAM18 (\( P_{mtlR} \)) is shown. The bacterial strains were grown in LB at 37°C. Glucitol (0.2%) and glucose (0.2%) were added at the OD\(_{600}\) of 0.4 and the \( \beta \)-galactosidase activity was measured after 1 h.

3.11.3. Deletion of the gutRBP genes encoding glucitol utilization system

Assuming that the inducibility of \( P_{mtlA} \) and \( P_{mtlR} \) by glucitol could be due to the interaction of the glucitol utilization system and mannitol PTS components, the complete gutRBP operon and its downstream gene, \( ydjE \) encoding a fructokinase, were replaced with a chloramphenicol acetyl transferase gene. The gene replacement cassette was constructed using oligonucleotides s6302/s6303 in a PCR with \( B. \ subtilis \) 168 for amplification of the upstream flanking gene, \( ydjC \). The downstream flanking gene, \( pspA \), was also amplified in a PCR by oligonucleotides s6304/s6305. The \( ydjC \) fragment was inserted into pMW363.1 via EcoRI/NheI (pKAM014). Next, the \( pspA \) fragment was inserted via AflIII/NdeI into pKAM014 to construct plasmid pKAM13. Strains 3NA and KM13 were transformed with pKAM13 harboring ‘\( ydjC\)-cat-pspA’ in order to construct a \( \Delta \)gutRBP\( ydjE::\)cat strain (KM39) and a \( \Delta \)mtlAF::ermC \( \Delta \)gutRBP\( ydjE::\)cat strain (KM40). Transformation of KM39 and KM40 by pKAM12 was carried out to construct strains KM39 pKAM12 and KM40 pKAM12. To both of the strains mannitol and glucitol were added to measure the \( \beta \)-galactosidase activity. Strain KM39 pKAM12 produced the same amount of \( \beta \)-galactosidase activity as 3NA pKAM12 (Fig. 3.18.A). KM39 pKAM12 showed 12,600
Results

Miller units β-galactosidase activity in the presence of mannitol, 8,000 Miller units in the presence of glucitol, and about 600 Miller units in the uninduced strain. Strain KM40 pKAM12 showed the same β-galactosidase activity as KM13 pKAM12 having 1,200 Miller units (Fig. 3.18.B). Apparently, the results revealed that the deletion of the glucitol utilization components had no influence on the \( P_{mtlA} \) activity.

![Fig. 3. 18. The activity of \( P_{mtlA} \) in deficient mutants of mannitol and glucitol utilization system. (A) β-galactosidase activity of the \( B. subtilis \) 3NA (wild type) and KM39 (\( \Delta gutRBPydjE \)) harboring pKAM12. (B) Production of β-galactosidase in the strains KM13 (\( \Delta mtlAFD \)) and KM40 (\( \Delta mtlAFD \ \Delta gutRBPydjE \)) containing pKAM12. Measurements of KM39 pKAM12 and KM40 pKAM12 were performed once.](image)

3.11.4. Growth of the mtl and gut mutants in minimal medium

Deletion of the \( \Delta gutRBPydjE \) genes revealed that the components of glucitol utilization system play no role in the induction of \( P_{mtlA} \) by glucitol. In addition to induction studies, the growth of the mannitol utilization deficient mutants was compared to deficient mutants of glucitol utilization system. The mtl and gut mutants were cultivated in minimal medium (broth I) harboring glucose, mannitol, or glucitol as the main carbon source, while the sodium citrate was removed from the bacterial culture. In this way, 1 OD\(_{600}\) of the overnight culture was inoculated into 5 ml minimal medium in a 100 ml baffled Erlenmeyer flask and the growth was measured after 16 h incubation at 37°C (shaked at 200 rpm).
Results

**Fig. 3.19.** The growth of deficient mutants of mannitol and glucitol utilization system strains. *B. subtilis* 3NA, KM12 (ΔmtlAF), KM13 (ΔmtlAFD), KM15 (ΔmtlR), KM37 (mtlD::cat), KM39 (ΔgutRBPydjE), and KM40 (ΔmtlAFD ΔgutRBPydjE) were cultivated in broth I harboring 1% glucose, mannitol, or glucitol as the main carbon source. The measurements were performed after 16 h of incubation at 37°C.

No growth was observed with the ΔmtlAF, ΔmtlAFD, and ΔmtlR mutants as well as with the ΔmtlAFD ΔgutRBPydjE double mutant in the presence of mannitol as the main carbon source (Fig. 3.19). As mentioned before, the ΔmtlD mutant was lysed in the presence of mannitol. However, glucitol as the main carbon source supported the growth of all of the mutants, except the ΔgutRBPydjE mutants, namely KM39 and KM40. Interestingly, the growth of the ΔmtlD mutant was half of the wild type strain in the presence of the glucitol showing the necessity of mannitol 1-phosphate dehydrogenase for the glucitol assimilation.
3.12. Carbon catabolite repression of \( P_{\text{mlA}} \) and \( P_{\text{mlR}} \)

3.12.1. \( P_{\text{mlA}} \) activity in the presence of different PTS sugars

Primary studies showed that the presence of glucose reduced \( P_{\text{mlA}} \) and \( P_{\text{mlR}} \) activities. Thus, different PTS sugars such as fructose, glucose, mannose, and sucrose were used to study their probable influence on \( P_{\text{mlA}} \) activity. To reduce the number of assays, \( P_{\text{mlA}} \) activity was studied in strain KM12 (\( \Delta\text{mtlAF} \) mutant) harboring pKAM12. In this strain, the activity of \( P_{\text{mlA}} \) was constitutive. Strain KM12 pKAM12 which was cultivated in LB with or without mannitol exhibited the same level of 13,900 – 15,100 Miller units \( \beta \)-galactosidase activity. Addition of glucose or fructose to the LB culture reduced \( \beta \)-galactosidase activity of KM12 pKAM12, while supplementation with mannose or sucrose had no influence on \( \beta \)-galactosidase activity (Fig. 3.20).

![Graph showing \( \beta \)-galactosidase activity](image)

**Fig. 3.20.** Carbon catabolite repression of \( P_{\text{mlA}} \) by different PTS sugars. \( \beta \)-galactosidase activity of strain KM12 pKAM12 (\( \Delta\text{mtlAF} \)) in LB supplemented by 0.2% of mannitol, fructose, glucose, mannose, or sucrose is represented. The desired sugar was added at the OD\(_{600}\) of 0.4 and \( \beta \)-galactosidase activity was measured 1 h after induction. No sugar was added to the control.

3.12.2. Activity of \( P_{\text{mlA}} \) in CcpA-dependent CCR mutants

Activity of \( P_{\text{mlA}} \) in the presence of glucose was investigated in CcpA-dependent CCR deficient mutants. At first, glucose repression of \( P_{\text{mlA}} \) was measured in \textit{B. subtilis} QB5223, a
Replacement of serine 46 in HPr by an alanine prevents the formation of the CcpA-HPr(S46~P) complex. Strain QB5223 (ptsH-S46A) was transformed with plasmid pKAM12 and β-galactosidase activity was measured after growth in LB supplemented with mannitol or with mannitol and glucose. The presence of glucose slightly reduced the β-galactosidase activity of QB5223 pKAM12 from 13,700 to 10,300 Miller units (Fig. 3.21). This result shows a weaker glucose repression effect in comparison with 3NA pKAM12. However, ptsH-S46A mutation encoding HPr-S46A did not completely relieve PmtlA from glucose repression. Thus, glucose repression of PmtlA was measured in a Δcrh mutant. For this purpose, strain TQ338 (Δcrh) was transformed with pKAM12. Addition of mannitol to the TQ338 pKAM12 culture showed a reduction of the β-galactosidase activity (about 8,100 Miller units) in comparison with 3NA pKAM12 (about 13,200 Miller units). Nevertheless, addition of glucose still reduced the PmtlA activity by 2.4-fold which was the same as with 3NA pKAM12. Given that neither ptsH-S46A nor Δcrh mutations in B. subtilis were able to abolish glucose repression, the PmtlA activity was measured in a ptsH-S46A Δcrh double mutant. Strain TQ338_S46 harboring the ptsH-S46A Δcrh double mutation was transformed with pKAM12. Comparing with 3NA pKAM12, induction of TQ338_S46 pKAM12 by mannitol resulted in a lower β-galactosidase activity. However, the basal β-galactosidase activity of TQ338_S46 pKAM12 culture was almost tripled in comparison with 3NA pKAM12 (Fig. 3.21). Similar to ptsH-S46A mutant, glucose repression was lower than in strain 3NA pKAM12 (about 1.3-fold). Apparently, deletion of crh or mutation of ptsH-S46A could not absolutely abolish the glucose repression of PmtlA. Hence, hprK encoding the HPrK/P enzyme was deleted. Deletion of the hprK gene led to no phosphorylation of HPr-S46 (or Crh-S46), and thereby inhibits the formation of CcpA-HPr(S46~P) or CcpA-Crh(S46~P) complex. For this purpose, strain TQ308 (ΔhprK) was transformed with pKAM12. TQ308 pKAM12 exhibited a reduced growth rate in LB as compared to 3NA pKAM12. The former reached an OD$_{600}$ of 0.9 after 1 h of induction by mannitol, while 3NA pKAM12 reached an OD$_{600}$ of 1.6–1.7 under same conditions. TQ308 pKAM12 showed a β-galactosidase activity of about 8,600 Miller units after cultivation in LB supplemented with mannitol, while its basal β-galactosidase activity was 800 Miller units in LB without mannitol. Moreover, glucose repression was still functional in TQ308 pKAM12 reducing the PmtlA activity by 1.65-fold. Therefore, glucose repression of PmtlA was measured in a ΔccpA mutant. Strain
TQ303 which is the CcpA-deficient mutant was transformed with pKAM12 using minimal medium supplemented with succinate and glutamate. The $P_{mtlA}$ activity in TQ303 pKAM12 was calculated from the cells grown in LB with or without mannitol. β-galactosidase activity of mannitol-induced TQ303 pKAM12 was lowered to 6,100 Miller units, whereas its basal β-galactosidase activity in LB remained of 500 Miller units (Fig. 3.21). Addition of the glucose strongly declined the β-galactosidase activity of TQ303 pKAM12 in LB with mannitol. Consequently, deletion of the CcpA-dependent CCR components did not completely abolish the glucose repression in $P_{mtlA}$. Hence, glucose repression in $P_{mtlR}$ was studied by the CcpA-dependent CCR mutants.

![Fig. 3.21. Catabolite repression of $P_{mtlA}$ in CcpA-dependent CCR deficient mutants. β-galactosidase activity of strains 3NA, QB5223 (ptsH-$S_{46}$A), TQ303 (ΔccpA), TQ308 (ΔhprK), TQ338 (Δcrh), and TQ338_S46 (ptsH-$S_{46}$A Δcrh) harboring pKAM12 ($P_{mtlA}$) in LB is shown. The desired sugar was added at the OD$_{600}$ of 0.4 and β-galactosidase activity was measured 1 h after induction. No sugar was added to the uninduced bacterial cultures.](image)

3.12.3. $P_{mtlR}$ activity in CcpA-dependent CCR mutants

The $mtlAFD$ operon is activated by MtlR; therefore, any variation of the MtlR amount in the cytoplasm could affect the $P_{mtlA}$ activity. Since identification of $P_{mtlR}$ indicated a cre site between -35 and -10 boxes of $P_{mtlR}$, the possibility of the binding of CcpA-HPr(S46-P) or CcpA-
Crh(S46-P) complex to $P_\text{mutR}$ was studied by the CcpA-dependent CCR deficient mutants. The strains TQ303 ($\Delta$ccpA) and the double mutant TQ338_S46 ($\Delta$crh ptsH-S46A) were transformed with pKAM18 (containing $P_\text{mutR}$-lacZ). β-galactosidase activity of TQ303 pKAM18 was about the same as with 3NA pKAM18 in LB with or without mannitol (Fig. 3.22). The main difference was noticed when both mannitol and glucose were added to the culture medium. In this case, β-galactosidase activity of TQ303 pKAM18 was doubled. Similar to TQ303 pKAM18, glucose repression of $P_\text{mutR}$ in TQ338_S46 pKAM18 was less than in 3NA pKAM18. However, the elevated basal β-galactosidase activity of TQ338_S46 pKAM18 makes the interpretation difficult. Consequently, mutations of the CcpA-dependent CCR components showed slightly influence on the glucose repression of $P_\text{mutA}$ and $P_\text{mutR}$.

![Graph showing β-galactosidase activity for different strains and conditions](image)

**Fig. 3.22.** Catabolite repression of $P_\text{mutR}$ in CcpA-dependent CCR deficient mutants. β-galactosidase activity of strains 3NA, TQ303 ($\Delta$ccpA), and TQ338_S46 (ptsH-S46A $\Delta$crh) harboring pKAM18 ($P_\text{mutR}$) is demonstrated. The strains were grown in LB and the desired sugar was added at the OD$_{600}$ of 0.4 and β-galactosidase activity was measured 1 h after induction.

**3.12.4. Deletion of the glucose-PTS transporter**

It was shown that deletion of the CcpA-dependent CCR components showed only a moderate reduction in the catabolite repression of $P_\text{mutA}$ and $P_\text{mutR}$. Therefore, the probable
influence of the deletion of \( \text{ptsG} \), encoding the \( \text{EIICBA}^{\text{Glc}} \) (glucose-PTS transporter) on the \( P_{\text{mtlA}} \) and \( P_{\text{mtlR}} \) activities was considered. For this purpose, strain MW373 was used which lacks the glucose PTS transporter (\( \Delta \text{ptsG} \)). Transformation of MW373 by pKAM12 and pKAM18 was carried out and the resulting transformants were subjected to mannitol (for induction) and glucose (for repression). Interestingly, \( \beta \)-galactosidase activity of MW373 pKAM12 in LB with mannitol was similar in the presence and absence of glucose (about 11,300 Miller units), while the inducibility of \( P_{\text{mtlA}} \) in \( \Delta \text{ptsG} \) mutant remained the same as in the wild type strain (Fig. 3.23.A). The presence of glucose did not alter the \( \beta \)-galactosidase activity of MW373 pKAM18 in LB supplemented with mannitol. The inducibility of \( P_{\text{mtlR}} \) in MW373 pKAM18 also remained the same as in the wild type strain (Fig. 3.23.B).

![Graph](image1.png)

**Fig. 3.23**. Catabolite repression of \( P_{\text{mtlA}} \) and \( P_{\text{mtlR}} \) in wild type and \( \Delta \text{ptsG} \) mutant. (A) \( \beta \)-galactosidase activity of strains 3NA and MW373 (\( \Delta \text{ptsG} \)) harboring pKAM12 (\( P_{\text{mtlA}} \)) is demonstrated. (B) \( \beta \)-galactosidase activity of the strains 3NA and MW373 (\( \Delta \text{ptsG} \)) harboring pKAM18 (\( P_{\text{mtlR}} \)) is represented. The desired sugar was added to the cells at the OD\(_{600}\) of 0.4 and the \( \beta \)-galactosidase activity was measured 1 h after induction.

### 3.13. Regulation of the MtlR activity via phosphorylation of MtlR domains

#### 3.13.1. Integration of \( P_{\text{mtlA}} \)-\( \text{lacZ} \) into the chromosome

Activity of MtlR was examined by mutation of the phosphorylation sites in the conserved domains of MtlR. To prevent a possible titration effect on the \( P_{\text{mtlA}} \) activity, the \( P_{\text{mtlA}} \)-\( \text{lacZ} \) fusion was integrated into the \( \text{amyE} \) gene encoding \( \alpha \)-amylase on the chromosome of \( B. \text{subtilis} \). For this purpose, plasmid pDG1730 was used consisting of the \( \text{amyE} \) gene disrupted by
spectinomycin resistance gene. The $P_{mtlA}$-lacZ fusion was amplified in a PCR by oligonucleotide s7455/s7481 using pKAM12 as a template. The PCR product was then inserted into pDG1730 DNA digested by HindIII and EcoRI and resulted in pKAM123. Afterwards, strain 3NA was transformed with plasmid pKAM123 harboring the amyE-$P_{mtlA}$-lacZ-spc-amyE cassette. The transformants were then selected based on spectinomycin resistance. The disruption of the amyE gene was confirmed on LB agar plate containing starch. Strain KM176 harboring the $P_{mtlA}$-lacZ fusion on the chromosome was subjected to mannitol (for induction) and glucose (for repression) in order to study the $P_{mtlA}$ activity. The basal $\beta$-galactosidase activity in uninduced KM176 was 69 Miller units. Addition of mannitol to LB induced the $P_{mtlA}$ activity in KM176 culture as indicated by the measurements of 776 Miller units $\beta$-galactosidase activity (Fig. 3.24). For this strain, simultaneous presence of mannitol and glucose in LB repressed the $P_{mtlA}$ activity about 3.6-fold.

### 3.13.2. Mutation of the PRDI domain

The influence of PRDI on the MtlR activity was studied by mutation of the putative phosphorylation sites at PRDI. At first, histidine 230 was mutated to alanine by a fusion PCR. PCRs from the chromosome of *B. subtilis* 168 were carried out using oligonucleotides s6949/s6868 and s6869/s6867. The fusion PCR was performed by oligonucleotides s6949/s6867 and the primary PCRs products. The $P_{mtlR}$-$mtlR$-H230A DNA fragment was then inserted into pJOE4786.1 digested by Smal and resulted in pKAM025. Next, pKAM025 DNA was digested by Xmal/SpeI and the 2.3 kb fragment was inserted into pKAM4 via the same restriction sites to construct pKAM127. Finally, strain KM15 ($\Delta mtlR$) was transformed with plasmid pKAM127 and the transformants were selected on mannitol minimal plates. The correct integration of $P_{mtlR}$-$mtlR$-H230A in to the chromosome of *B. subtilis* led to the deletion of the erythromycin resistance gene. Strain KM210 ($mtlR$-H230A) was subsequently transformed with pKAM123 in order to integrate $P_{mtlA}$-lacZ into the chromosome at the amyE gene (strain KM214). The $\beta$-galactosidase activity of the latter strain, namely KM214, was measured by the addition of mannitol in the presence and absence of glucose in the culture media. No significant difference was observed in the $\beta$-galactosidase activity of KM176 ($mtlR$) and KM214 ($mtlR$-H230A) (Fig.
3.24). Afterwards, the second phosphorylation site of PRDI, namely histidine 289, was mutated to alanine by a fusion PCR. PCRs were performed from B. subtilis 168 chromosome using oligonucleotides s6949/s6870 and s6871/s6867. Fusion PCR was accomplished using oligonucleotides s6949/s6867 and the primary PCR products. The \(P_mtlR-mtlR-H289A\) fragment was then inserted into pJOE4786.1 via \(SmaI\) restriction sites and created plasmid pKAM026. Digestion of the pKAM026 DNA by \(XmaI/SpeI\) was carried out and the 2.3 kb fragment was inserted into pHM31 (see appendices) via the \(XmaI/NheI\) restriction sites and resulted in pKAM68. Integration of \(P_mtlR-mtlR-H289A\) into the 3NA chromosome was accomplished in two steps based on histidine auxotrophy (158). First, plasmid pHM30 (see appendices) harboring a spectinomycin resistance gene was integrated into the chromosome of KM15. This integration disrupted the last gene of the \(his\) operon, \(hisI\), in which the spectinomycin resistance gene was integrated into the chromosome. Selection of the transformants was performed on LB\(_{spc}\) plates (strain KM162). Afterwards, the histidine auxotrophic mutant, i.e. strain KM162, was transformed with pKAM68 containing an intact \(hisI\) gene as well as \(P_mtlR-mtlR-H289A\). Selection of the transformants harboring the \(mtlR-H289A\) mutation was performed on Spizizen minimal medium plates lacking histidine. In this way, strain KM165 was constructed in which \(P_mtlR-mtlR-H289A\) resided downstream of the \(his\) operon. Then, transformation of KM165 by pKAM123 was carried out in order to integrate the \(P_mtlA-lacZ\) fusion into the \(amyE\) locus. The newly constructed strain was called KM179. Induction of the KM179 strain (\(mtlR-H289A\)) indicated a lower \(\beta\)-galactosidase activity, about 377 Miller units, compared to KM176 culture with a \(\beta\)-galactosidase activity of about 776 Miller units (wild type \(mtlR\)) (Fig. 3.24). Interestingly, the glucose repression in KM179 culture with a \(\beta\)-galactosidase activity of about 16 Miller units \(\beta\)-galactosidase activity was stronger than in KM176 with 215 Miller units. Finally, the \(P_mtlA\) activity was measured in the \(mtlR-H230A-H289A\) double mutant. The \(P_mtlR-mtlR-H230A-H289A\) DNA fragment was amplified by using pKAM025 as a template and oligonucleotides s6949/s6870 and s6871/s6867 in PCRs. Next, fusion PCR was accomplished using oligonucleotides s6949/s6867 and the primary PCR products. The \(P_mtlR-mtlR-H230A-H289A\) PCR fragment was inserted into pJOE4786.1 digested by \(SmaI\) (pKAM027). Next, pKAM027 DNA was digested by \(XmaI/SpeI\) and the 2.3 kb fragment was inserted into pKAM4 via \(XmaI/SpeI\) restriction sites and created plasmid pKAM129. Strain KM212 was constructed by
transformation of strain KM15 (ΔmtlR) with pKAM129. Afterwards, the \( P_{mtlA-lacZ} \) fusion on pKAM123 was integrated into the \( amyE \) locus of strain KM212 resulting in strain KM216. Induction of KM216 expressing \( mtlR\)-H230A H289A by mannitol indicated a similar β-galactosidase activity compared to KM179 (\( mtlR\)-H289A). The glucose repression in KM216 was also stronger than in KM176 (wild type \( mtlR \)) (Fig. 3.24).

![Graph showing β-galactosidase activity of different strains](image)

**Fig. 3.24.** Activity of \( P_{mtlA} \) in the \( mtlR \) mutants. β-galactosidase activity of strains KM176 (\( mtlR \)), KM179 (\( mtlR\)-H289A), KM213 (\( mtlR\)-H342D), KM214 (\( mtlR\)-H230A), and KM216 (\( mtlR\)-H230A H289A) in LB is shown. All of the strains contain an integrated \( P_{mtlA-lacZ} \) fusion in their \( amyE \) locus. The desired sugar was added at the OD\(_{600}\) of 0.4 and β-galactosidase activity was measured 1 h after induction.

### 3.13.3. Mutation of the PRDII domain

Histidine 342 located at PRDII domain was exchanged by an aspartic acid in order to construct a mimic of a phosphorylated histidine. For this purpose, \( P_{mtlR-mtlR-H342D} \) was amplified by oligonucleotides s6949/s6865 and s6866/s6867 in PCRs. Afterwards, a fusion PCR was carried out by oligonucleotides s6949/s6867 and the primary PCRs products. The final \( P_{mtlR-mtlR-H342D} \) fragment was blunt inserted into pJOE4786.1 which was already cut by \( SmaI \). The resulting plasmid, pKAM024, was digested by \( XmaI \) and \( SpeI \), and the 2.3 kb fragment was inserted into the pKAM4 via \( XmaI/SpeI \) restriction sites and led to construction of pKAM126.
Afterwards, strain KM15 (ΔmtlR) was transformed with pKAM126. The transformants expressing mtlR-H342D were selected on mannitol minimal plates. The newly constructed strain was named KM209. By integration of the \( P_{mtlA-lacZ} \) fusion into the \( amyE \) locus of KM209, strain KM213 was constructed. Induction of KM213 by mannitol in LB showed approximately 800 Miller units \( \beta \)-galactosidase activity resembling KM176. Besides, the basal \( \beta \)-galactosidase activity of KM213 expressing mtlR-H342D was doubled compared to KM176 (wild type \( mtlR \)). Finally, addition of glucose slightly reduced the \( \beta \)-galactosidase activity of KM213 (Fig. 3.24).

### 3.14. Operators of \( P_{mtlA} \) and \( P_{mtlR} \)

#### 3.14.1. Alignment of the \( P_{mtlA} \) and \( P_{mtlR} \) putative activator binding sites

Induction of \( P_{mtlA} \) and \( P_{mtlR} \) showed that both of the promoters are activated by MtlR. Besides, sequence analyses revealed incomplete inverted repeats residing upstream of the -35 boxes in \( P_{mtlA} \) and \( P_{mtlR} \). To find the exact MtlR binding site of \( P_{mtlA} \) and \( P_{mtlR} \), the upstream sequences of the -35 boxes in \( P_{mtlA} \) and \( P_{mtlR} \) were aligned. As depicted in Fig. 3.25, 11 bp flanking sites of the incomplete inverted repeats were highly similar. This sequence was longer than the MtlR binding site so far predicted by Watanabe et al. (239).

![Fig. 3.25. Alignment of the \( P_{mtlA} \) and \( P_{mtlR} \) -35 upstream sequences. The MtlR binding site is predicted by Watanabe et al. (239).](image-url)
3.14.2. Fusion of the $P_{mtlA}$ upstream sequence to the $P_{mtlR}$ core elements

The putative MtlR binding sites of $P_{mtlA}$ and $P_{mtlR}$ were compared by the fusion of $P_{mtlA}$ upstream sequence to $P_{mtlR}$ core elements. For this purpose, PCRs from the chromosome of B. subtilis 168 were performed by oligonucleotides s6209/s6798 and s6799/s6392. The products of primary PCRs were then fused by a PCR using oligonucleotides s6209/s6392. The final $P_{mtlA}$-$P_{mtlR}$ fragment was then digested by NheI and AflIII and inserted into pSUN279.1 and created pKAM51. Fig. 3.26.A demonstrates the sequence of the hybrid promoter. Plasmid pKAM51 was used for transformation of B. subtilis 3NA, which was then induced by 0.2% mannitol in LB. β-galactosidase activity of 3NA pKAM51 was about 152 Miller units in LB supplemented with mannitol, whereas the basal β-galactosidase activity was only 47 Miller units after cultivation in LB (Fig. 3.26.B). In comparison with 3NA pKAM18 carrying $P_{mtlR}$, the β-galactosidase activity of 3NA pKAM51 was doubled in the both induced and uninduced cultures. This could be due to a higher affinity of MtlR to the $P_{mtlA}$ operator.

Fig. 3.26. (A) The sequence of the $P_{mtlA}$-$P_{mtlR}$ fusion on pKAM51. (B) β-galactosidase activities of the induced and uninduced 3NA pKAM18 and 3NA pKAM51 strains.

3.14.3. Shortening of the 5’-end of $P_{mtlA}$

In section 3.3, it was shown that shortening of 20 bp from the $P_{mtlA}$ 5’-end had no effect on the $P_{mtlA}$ activity on pKAM9. To identify the 5’ boundary of $P_{mtlA}$ in vivo, shortening of the 5’-end of $P_{mtlA}$ was gradually performed in 2 bp blocks (Fig. 3.27.A). For these attempts, pKAM12
was chosen as a template and oligonucleotides s6726/s6213 (pKAM43), s6792/s6213 (pKAM48), s6793/s6213 (pKAM49), s6829/s6213 (pKAM57), s6830/s6213 (pKAM58), and s6210/s6213 (pKAM59) were used in PCRs. The obtained promoter fragments were then inserted into pSUN279.2 via NheI/AflII. The constructs are shown in Fig. 3.27.A. After transformation of 3NA by the resulting plasmids, induction of strain 3NA harboring pKAM43, pKAM48, or pKAM49 by mannitol showed no significant difference in β-galactosidase activity compared to 3NA pKAM12 culture (Fig. 3.27.B). Removal of additional 2 bp showed a reduction in β-galactosidase activity of 3NA pKAM57 and 3NA pKAM59. Nevertheless, $P_{mtlA}$ was still inducible in 3NA pKAM57 and pKAM59 by 19-fold and 21-fold, respectively, which were similar to 3NA pKAM12 (22-fold induction) (Fig. 3.27.B). Finally, 3NA pKAM58 had a low β-galactosidase activity and indicated no inducibility. In fact, the results of the 5'-end shortening of $P_{mtlA}$ were in line with the conserved -35 upstream sequence of $P_{mtlA}$ and $P_{mtlR}$ (section 3.14.1). Therefore, MtlR binding site likely begins at the position -83 with respect to the transcription start site.

3.14.4. Mutations between the MtlR binding site and -35 box of $P_{mtlA}$

Shortened $P_{mtlA}$ constructs revealed the 5’-end of MtlR binding site. However, the 3’-end of the MtlR binding site remained unclear. Therefore, identification of the 3’-end of the MtlR binding site was started by exchanging 5 bp blocks to their complementary sequence (see Fig. 3.27.A). In this way, different $P_{mtlA}$ constructs were generated by PCR from pKAM12 using oligonucleotides s6688/s6213 (pKAM27), s7065/s6213 (pKAM84), and s7091/s6213 (pKAM92). Also, fusion PCRs were carried out for construction of pKAM45 and pKAM52. PCRs were performed from pKAM12 using oligonucleotides s6209/s6728 and s6729/s6213. Fusion PCR was carried out using primary PCRs products and oligonucleotides s6209/s6213 (pKAM45). For pKAM52, oligonucleotides s6209/s6800 and s6801/s6213 were applied in PCRs. These PCR products were then used as templates for the final PCR by s6209/s6213. Strain 3NA was then transformed with pKAM27, pKAM45, pKAM52, pKAM84, or pKAM92. In comparison with 3NA pKAM12, induced 3NA pKAM52 showed a reduced β-galactosidase activity with about 6,400 Miller units (Fig. 3.27.B). Also, the basal β-galactosidase activity of
3NA pKAM52 was 3-fold lower than of 3NA pKAM12. Strains 3NA pKAM45 and 3NA pKAM84 showed 8,500 and 7,400 Miller units β-galactosidase activity, respectively, whereas their basal β-galactosidase activity were 400 and 300 Miller units, respectively.

**Fig. 3. 27.** (A) Partial sequence of \( P_{\text{mtlA}} \) on pKAM12 and the constructs thereof. The promoter -35 and -10 boxes are enclosed by rectangles, while a single C residue (bold capital letter) is the transcription start site. The putative cre site is underlined. The first base pair of each shortened promoter is shown by a box and an arrow. The base pair exchanges are highlighted in dark gray in pKAM27 and pKAM92, in light gray pKAM45 and pKAM84, or enclosed by a rectangle in pKAM52. (B) β-galactosidase activity of strain 3NA containing pKAM12, pKAM27, pKAM43, pKAM45, pKAM48, pKAM49, pKAM52, pKAM57, pKAM58, pKAM59, pKAM84, and pKAM92.
Induced 3NA pKAM27 showed a stronger β-galactosidase activity reduction (aprox. 4,200 Miller units) in comparison with 3NA containing pKAM52, pKAM45, and pKAM84. However, the basal β-galactosidase activity of 3NA pKAM27 remained at 300 Miller units (Fig. 3.27.B). Finally, the base pairs located at the inverted repeat upstream of -35 in \( P_{\text{mtlA}} \) mutant were exchanged to their complementary sequence to create pKAM92. Addition of mannitol to 3NA pKAM92 indicated slight amount of β-galactosidase activity in which \( P_{\text{mtlA}} \) was uninducible. Altogether, base pair exchanges between -35 box and the predicted MtlR binding site did not reveal a clear result. Thus, identification of the 3’-end of MtlR binding site in \( P_{\text{mtlA}} \) was continued by construction of hybrid promoters (Fig. 3.27.B).

### 3.14.5. Construction of hybrid promoters

#### 3.14.5.1. Fusion of the putative ManR binding site of \( P_{\text{manP}} \) to \( P_{\text{mtlA}} \) core elements

To identify the 3’-end of the MtlR binding site, different hybrid promoters were constructed. At first, it was necessary to have a well-known promoter in which the regulator binding site was well understood. Then, this promoter would be used as a platform for identification of the MtlR binding site. Therefore, the promoter of the mannose operon \( (P_{\text{manP}}) \) in \( B. \text{subtilis} \) was exploited. Plasmids pKAM12 and pSUN284.1 (214), were used as the controls of \( P_{\text{mtlA}} \) and \( P_{\text{manP}} \) activities, respectively. Plasmid pSUN284.1 is a plasmid similar to pKAM12 based on pBS72 replicon in \( B. \text{subtilis} \), but it carries \( P_{\text{manP}} \) rather than \( P_{\text{mtlA}} \). Strain 3NA pSUN284.1 was induced by mannose, while 3NA pKAM12 was induced by mannitol. Induction of 3NA pSUN284.1 showed 15,000 Miller units β-galactosidase activity, while the basal β-galactosidase activity was only about 2,000 Miller units (Fig. 3.28.B). Subsequently, the activator binding site of \( P_{\text{manP}} \) was fused to the \( P_{\text{mtlA}} \) core elements (Fig. 3.28.A). For this purpose, the upstream region of -35 box in \( P_{\text{mtlA}} \) was replaced with the putative ManR binding site of \( P_{\text{manP}} \) to obtain the hybrid promoter 11 \( (P_{\text{HP11}}) \). To fuse the \( P_{\text{manP}} \) fragment to the \( P_{\text{mtlA}} \) core elements, oligonucleotides s6504/s6508 and s6509/s6507 were used in PCRs from \( B. \text{subtilis} \) 168 genomic DNA. Fusion PCR was performed by oligonucleotides s6504/s6507 using primary PCR products.
as a template. By insertion of the $P_{HP11}$ fragment via NheI/AflII restriction sites into pSUN279.2, the precursor of pSUN284.1, plasmid pKAM25 was constructed.

![Fig. 3. 28. (A) The sequences of the $P_{manP} - P_{mld}$ hybrid promoters. The $P_{mld}$ sequence is shown by the capital letter, while $P_{manP}$ by the bold small letter. (B) $\beta$-galactosidase activity of *B. subtilis* 3NA containing pKAM12 ($P_{mld}$), pKAM23 ($P_{HP9}$), pKAM25 ($P_{HP11}$), pKAM29 ($P_{HP13}$), pKAM30 ($P_{HP13}$), pKAM62 ($P_{HP20}$), and pSUN284.1 ($P_{manP}$). All of the strains were induced by 0.2% mannose except strain 3NA pKAM12, which was induced by 0.2% mannitol.](image)

After transformation of 3NA by pKAM25, the addition of 0.2% mannose to the 3NA pKAM25 culture showed that 3NA pKAM25 exhibited half of the $\beta$-galactosidase activity of 3NA pKAM12, although the basal $\beta$-galactosidase activity was doubled (1,200 Miller units). In the next step, the first base pair of the -35 box in $P_{HP11}$ was replaced with its counterpart from $P_{manP}$ resulting in promoter $P_{HP13}$. Construction of $P_{HP13}$ was performed using oligonucleotides.
s6504/s6652 and s6653/s6507 in PCRs from the chromosome of \textit{B. subtilis} 168. The fusion PCR by using oligonucleotides s6504/s6507 and primary PCR products resulted in $P_{HP13}$ which was next inserted into pSUN279.2 via NheI/AflII and created pKAM30. Induction of 3NA pKAM30 with mannose showed a low $\beta$-galactosidase activity, although the $P_{HP13}$ activity was inducible by 4-fold. Afterwards, additional base pairs of the -35 box of $P_{HP13}$ were replaced with the $P_{manP}$ counterparts by construction of $P_{HP12}$, and $P_{HP20}$. Plasmids pKAM29 ($P_{HP12}$) and pKAM62 ($P_{HP20}$) were constructed by fusion PCRs from the genomic DNA of \textit{B. subtilis} 168. Oligonucleotides s6504/s6608 and s6609/s6507 (pKAM29) as well as s6504/s6855 and s6507/s6856 (pKAM62) were used for PCRs. Fusion PCRs were carried out using primary PCR products and oligonucleotides s6504/s6507 in both cases. The basal $\beta$-galactosidase activity of 3NA pKAM29 with 4 base pairs exchanged in the -35 box was about 1,600 Miller units, while the induced cells showed 7,000 Miller units $\beta$-galactosidase activity. Strain 3NA pKAM62 with 5 base pairs exchanged in the -35 box of hybrid promoter had a higher $\beta$-galactosidase activity than 3NA pKAM29. In 3NA pKAM62, 12,800 Miller units $\beta$-galactosidase activity was measured in the presence of mannose, whereas basal $\beta$-galactosidase activity was 1,800 Miller units. Finally, $P_{HP9}$ was constructed in which the complete sequence of the -35 box was replaced with the $P_{manP}$ sequence. To construct pKAM23 harboring $P_{HP9}$, oligonucleotides s6504/s6510 and s6511/s6507 were used for PCRs from \textit{B. subtilis} 168 genome. The fusion PCR was performed by the primary PCR products, as template, and the s6504/s6507 oligonucleotides. Induction of 3NA pKAM23 indicated a similar $\beta$-galactosidase activity to pSUN284.1, although the basal $\beta$-galactosidase activity of 3NA pKAM23 was significantly lower (Fig. 3.28.A). Altogether, it is assumed that the ManR binding site overlaps the -35 hexamer. Comparison of the ATTTTA hexamer, the reported -35 box of $P_{manP}$ (214), with the consensus $\sigma^{A}$-type -35 box (TTGACA) pointed out that $P_{manP}$ probably has not a real -35 box. Indeed, different promoter structures of $P_{manP}$ and $P_{nilA}$ makes it difficult to construct functional hybrid promoters. Thus, the promoter of licBCAH operon was exploited for construction of hybrid promoters.
3.14.5.2. Comparison of the putative activator binding sites in $P_{mtlA}$ and $P_{licB}$

To find a new platform for construction of hybrid promoters, the promoter of the $licBCAH$ operon ($P_{licB}$) was considered. The $licBCAH$ operon encodes the PTS components necessary for utilization of $\beta$-glucans (221). This promoter is activated by a specific PRD-containing regulator, LicR, in response to the presence of lichenan, or its hydrolysates such as cellobiose (221, 222). The alignment of the upstream sequences of $P_{mtlA}$ and $P_{licB}$ -35 boxes showed a similar structure of the two promoters (Fig. 3.29). In fact, the heptamer spacer between the probable activator binding site and the -35 box in $P_{mtlA}$ was similar to $P_{licB}$. Consequently, $P_{licB}$ core elements were fused to upstream sequence of $P_{mtlA}$ -35 box (Fig. 3.30.A).

![Fig. 3.29. Comparison of the upstream sequence of $P_{mtlA}$ and $P_{licB}$ -35 boxes. The putative MtlR binding site in $P_{mtlA}$ was deduced from the alignment of $P_{mtlA}$ and $P_{mtlR}$, while the LicR binding site of $P_{licB}$ was reported by Tobisch et al. (39, 40).](image)

3.14.5.3. Fusion of the upstream sequence of -35 box of $P_{mtlA}$ to $P_{licB}$ core elements

At first, $P_{licB}$ was inserted upstream of the lacZ gene on pSUN279.2. Oligonucleotides s7614/s7615 were used for PCR from the B. subtilis 168 chromosome and the amplified $P_{licB}$ fragment was then inserted into pSUN279.2 via NheI/AflIII restriction site to construct pKAM160 (Fig. 3.30.A). Induction of 3NA pKAM160 with cellobiose harboring $P_{licB}$-lacZ showed 1,600 Miller units $\beta$-galactosidase activity, while the basal $\beta$-galactosidase activity amounted to 300 Miller units (Fig. 3.30.B).

Fig. 3. (A) The sequences of the \( P_{mtlA} \)-\( P_{licB} \) hybrid promoters. The \( P_{mtlA} \) sequence is shown by capital letters, while the \( P_{licB} \) sequence by small letters. (B) \( \beta \)-galactosidase activity of \( B. subtilis \) 3NA harboring pKAM160 (\( P_{licB} \)), pKAM161 (\( P_{HP41} \)), pKAM162 (\( P_{HP42} \)), pKAM176 (\( P_{HP43} \)). Strain 3NA pKAM160 was induced by 0.2% cellobiose, while 3NA pKAM161, 3NA pKAM162, and 3NA pKAM176 were induced by 0.2% mannitol.

Next, the upstream region of \( P_{mtlA} \) beginning exactly at the 5’-end of -35 box was fused to \( P_{licB} \) core elements. Oligonucleotides s6209/s7617 were used to amplify the \( P_{mtlA} \) fragment from \( B. subtilis \) 168 genome, whereas oligonucleotides s7616/s7615 were used for amplification of \( P_{licB} \) fragment by PCR from the chromosome of \( B. subtilis \) 168. Digestion of the two fragments by \( BsaI \) was followed by a ligation reaction. Then, the ligated fragments were amplified by oligonucleotides s6209/s7615 in a PCR. Plasmid pKAM161 was constructed by the insertion of the \( P_{mtlA}-P_{licB} (P_{HP41}) \) fragment into pSUN279.2 via \( NheI/AflII \) restriction sites. The induced 3NA pKAM161 containing \( P_{HP41} \) showed half of the \( \beta \)-galactosidase activity of 3NA pKAM160 with approximately 860 Miller units. However, the \( P_{HP41} \) remained inducible by mannitol. Afterwards, a change of two base pairs in the heptamer (CAA to GAG) was carried out to construct the hybrid
Results

For this purpose, oligonucleotides s7714/s7615 were used in a PCR from the genome of \textit{B. subtilis}. By insertion of the PCR fragment into pSUN279.2 via \textit{NheI/AflII}, the final vector, called pKAM176, was constructed. Induction of this strain showed no considerable changes to the strain containing \( P_{\text{HP41}} \). Subsequently, next hybrid promoter, \textit{i.e.} \( P_{\text{HP42}} \), was constructed supposing that the heptamer spacer does not belong to the MtlR binding site. Thus, the -35 box and the upstream heptamer sequence of \( P_{\text{licB}} \) were fused to the putative MtlR binding site in \( P_{\text{mtlA}} \). Construction of \( P_{\text{HP42}} \) was carried out by PCRs from the chromosome of \textit{B. subtilis} 168 using oligonucleotides s6209/s7618 and s7619/s7615. The PCR products were then exploited in a fusion PCR using oligonucleotides s6209/s7615. Plasmid pKAM162 was constructed by the insertion of \( P_{\text{HP42}} \) into pSUN279.2 via \textit{NheI} and \textit{AflII}. Surprisingly, addition of mannitol to the 3NA pKAM162 culture did not induce \( P_{\text{HP42}} \) and its \( \beta \)-galactosidase activity was about 80 to 100 Miller units (Fig. 3.30.B). Altogether, shortening of the \( P_{\text{mtlA}} \) 5’-end and construction of hybrid promoters revealed the putative MtlR binding site (TTTTTTAAAAAN\textsubscript{20}AGTCCTCTTACTTT).

3.14.5.4. Increasing the distance between putative MtlR binding site and -35 box in \( P_{\text{mtlA}} \)

To show whether the putative MtlR binding site overlaps the -35 box, as observed in \( P_{\text{manP}} \), the distance between the -35 box and the putative MtlR binding site in \( P_{\text{mtlA}} \) was increased (Fig. 3.31.A). At first, \( P_{\text{mtlA+10}} \) was constructed in which the MtlR binding site was relocated 10 bp farther to -35 box than in \( P_{\text{mtlA}} \). This distance corresponds to a complete turn of B-DNA double helix. Oligonucleotides s6209 and s7548 were used in a PCR from pKAM12 in order to amplify the \( P_{\text{mtlA+10}} \) fragment. The \( P_{\text{mtlA+10}} \) fragment was then inserted into pKAM12 via \textit{NheI} and \textit{MunI} restriction sites to construct pKAM145. Strain 3NA pKAM145 showed only about 800 Miller units \( \beta \)-galactosidase activity in LB with mannitol, while the basal \( \beta \)-galactosidase activity was about 100 Miller units in LB without mannitol (Fig. 3.31.B). Although the distance between MtlR and RNAP was increased, \( P_{\text{mtlA+10}} \) remained inducible by 8-fold. By addition of a single base pair, the inserted sequence between putative MtlR binding site and the -35 box increased to 11 bp \( (P_{\text{mtlA+11}}) \).
A

Fig. 3.31. Increasing the distance between putative MtlR binding site and -35 box of \( P_{\text{mtlA}} \). (A) Upstream sequence of the -35 box of \( P_{\text{mtlA}} \) on pKAM12 and the constructs thereof. (B) \( \beta \)-galactosidase activity of strain 3NA harboring pKAM12 (\( P_{\text{mtlA}} \)), pKAM145 (\( P_{\text{mtlA+10}} \)), pKAM167 (\( P_{\text{mtlA+11}} \)), and pKAM168 (\( P_{\text{mtlA+9}} \)).

Amplification of \( P_{\text{mtlA+11}} \) was performed by a PCR from pKAM12 using oligonucleotides s6209 and s7678. The \( P_{\text{mtlA+11}} \) fragment was inserted into pKAM12 via \textit{NheI} and \textit{MunI} restriction sites and created pKAM167. In the presence of mannitol in LB, \( \beta \)-galactosidase activity of 3NA pKAM167 was reduced to about 400 Miller units. Without mannitol, the basal \( \beta \)-galactosidase activity of 3NA pKAM167 was only about 100 Miller units. This indicated a 4-fold induction of \( P_{\text{mtlA+11}} \) activity. In contrast to \( P_{\text{mtlA+11}} \), a single base pair was deleted in \( P_{\text{mtlA+10}} \) to construct \( P_{\text{mtlA+9}} \). Amplification of \( P_{\text{mtlA+9}} \) was accomplished by a PCR from pKAM12 using
Results

oligonucleotides s6209 and s7679. The \( P_{mlA+9} \) fragment was then inserted into pKAM12 through \( NheI \) and \( MunI \) restriction sites resulting in pKAM168. Only about 150 Miller units \( \beta\)-galactosidase activity was measured when 3NA pKAM168 was cultivated in LB with or without mannitol (Fig. 3.31.B). In other words, by insertion of 9 bp between the -35 box and the putative MtlR binding site, the \( P_{mlA+10} \) activity became constitutive at a very low level. Altogether, this study showed that \( P_{mlA} \) remained inducible, even though MtlR binding site was relocated a complete DNA helix turn farther than the wild type locus. This shows that the MtlR binding site does not overlap the -35 box.

3.14.5.5. Confirmation of MtlR binding site by \( P_{mlA} \)-\( P_{manP} \) fusion

To confirm the 3'-end of MtlR binding site obtained by construction of \( P_{mlA} \)-\( P_{licB} \) hybrids, the MtlR binding site of \( P_{mlA} \) was fused to the \( P_{manP} \) core elements (Fig. 3.32.A). As a control, the \( P_{mlA} \) sequence containing MtlR binding site and the -35 box was fused in a PCR to the sequence between -35 and -10 boxes of \( P_{manP} \). PCRs from \( B.\ subtilis \) 168 genome were performed using oligonucleotides s6209/s6861 and s6862/s6954. Next, primary PCRs products were used in a fusion PCR by oligonucleotides s6209/s6954. The PCR product, denoted \( P_{HP23} \), was then inserted into pSUN279.2 via \( NheI/AflII \) restriction sites to create pKAM65. Addition of the mannitol to 3NA pKAM65 culture considerably activated \( P_{HP23} \) by leading to 11,000 Miller units \( \beta\)-galactosidase activity, whereas the basal \( \beta\)-galactosidase activity was only 1,200 Miller units (Fig. 3.32.B). Subsequently, the -35 box and 3 bp upstream of the -35 box in \( P_{HP23} \) were replaced with the \( P_{manP} \) counterparts (see \( P_{HP44} \); Fig. 3.32.A). Amplification of \( P_{HP44} \) was performed by oligonucleotides s7800 and s6954 in a PCR from \( B.\ subtilis \) 168 chromosome. The \( P_{HP44} \) fragment was then inserted into pSUN279.2 via \( NheI/AflII \) (construct pKAM185). Induction of 3NA pKAM185 by mannitol showed 4,200 Miller units \( \beta\)-galactosidase activity in LB, while the basal \( \beta\)-galactosidase activity was only about 300 Miller units (Fig. 3.32.B). In other words, \( P_{HP44} \) was inducible by 14-fold which was even higher than \( P_{HP23} \) (9-fold). However, the weaker activity of \( P_{HP44} \) in comparison with \( P_{HP23} \) could be due to the absence of an optimal -35 box identical to the \( \sigma^A \)-type consensus sequence.

The MtlR binding site located at \(P_{mtlA}\) was characterized by the construction of hybrid promoters \(in vivo\). Nevertheless, to confirm the identified MtlR binding site \(in vitro\), it was necessary to carry out DNase I footprinting. Prior to perform the DNase I footprinting, the electrophoretic mobility shift assay was considered to find out the optimized \(in vitro\) conditions for the binding of MtlR to \(P_{mtlA}\). Briefly, in an electrophoretic mobility shift assay, the migration of the labeled DNA band is compared to the DNA-protein complex band by a nondenaturing polyacrylamide gel electrophoresis (native PAGE). Formation of the DNA-protein complex results in a slower migration of the complex; therefore, a shifted band appears compared with the labeled DNA without protein as a control. In this study, the Cy5-labeled \(P_{mtlA}\) was mixed with the purified MtlR and loaded onto the native PAGE. To yield high amount of purified MtlR, different strategies were exploited for protein expression and purification.
3.14.6.1. Expression of mtlR-His$_6$ in B. subtilis KM12

To produce MtlR in B. subtilis, mtlR was inserted downstream of P$_{mtlA}$ on pKAM12. Furthermore, a His$_6$-tag was fused to the C-terminus of MtlR to facilitate the purification of the produced MtlR. The mtlR-His$_6$ fragment was amplified from the genome of B. subtilis 168 using oligonucleotides s6686 and s6687. Due to the presence of a Ndel restriction site inside the mtlR sequence, the forward oligonucleotide primer was extended towards the ribosomal binding site of lacZ on pKAM12 in order to insert the mtlR-His$_6$ via AflII/XmaI into pKAM12 to construct plasmid pKAM39. As a host, B. subtilis KM12 (ΔmtlAF) was used in which P$_{mtlA}$ was constitutive (section 3.10.2).

For production of MtlR, the strain was grown overnight in LB at 37°C. After lysis of KM12 pKAM39 by high pressure homogenizer, soluble and insoluble fractions of the bacterial lysate were analyzed on SDS-PAGE which showed a high amount of MtlR-His$_6$ in the insoluble fraction (Fig. 3.33.A). This could be due to inclusion bodies formation. Therefore, the bacterial
culture was cultivated at 30°C and 25°C in order to reduce the formation of inclusion body. As shown in Fig. 3.33.B, MtlR-His6 was produced in less amount of insoluble protein at 25°C. Therefore, KM12 pKAM39 was incubated at 25°C overnight and the bacterial culture harvested for purification of MtlR-His6. Purification of the MtlR-His6 was carried out using Ni-NTA agarose. The flow-through and the wash fractions were analyzed on SDS-PAGE (Fig. 3.34). Elution fraction 2 contained the highest yield of purified MtlR-His6 with about 4.9 mg/ml. For the electrophoretic mobility shift assay, the purified MtlR-His6 (elution fraction 2) was diluted to 49 µg/ml using resuspension buffer I (NaH₂PO₄ 50 mM, NaCl 300 mM, pH 8). The Pₘₐₐ DNA fragment was Cy5-labeled by PCR using oligonucleotides s6209 and 5’-Cy5 s5960 and pKAM12 as a template. Afterwards, the electrophoretic mobility shift reaction was performed by mixing MtlR-His6 and Cy5-Pₘₐₐ. After incubation on ice for 15 min, the reactions were loaded onto a 6% native polyacrylamide gel. The results indicated a weak shifted band in the presence of MtlR-His6 (Fig. 3.35). Next, the shift reaction was incubated at the room temperature and on ice. It is shown that the amount of shifted fragment was lower by increasing the temperature (Fig. 3.35). Thereafter, all of the reactions were incubated on ice for at least 15 min.

**Fig. 3.34.** Purification of MtlR-His6 using Ni-NTA agarose. KM12 pKAM39 was cultivated in LB overnight at 25°C. The cells were disrupted by high pressure homogenizer. Resuspension, washing and elution buffers I were used for affinity chromatography. **Lane L:** Roti®-Mark Standard; **lane 1:** flow-through; **lane 2:** wash fraction 1; **lane 3:** wash fraction 2; **lane 4:** elution fraction 1; **lane 5:** elution fraction 2; **lane 6:** elution fraction 3; **lane 7:** elution fraction 4.
Results

**Fig. 3.** Electrophoretic mobility shift of Cy5-\(P_{mtlA}\) DNA fragment (33 fmol) by purified MtlR-His\(_6\) (49 ng) at room temperature and on ice. The reaction was carried out using shift buffer A in a total volume of 10 \(\mu\)l. After incubation on ice for 15 min, the Cy5-\(P_{mtlA}\) and MtlR-His\(_6\) mixture was loaded on 6\% native polyacrylamide gel. **Lane 1:** Cy5-\(P_{mtlA}\); **lane 2:** Cy5-\(P_{mtlA}\) and MtlR-His\(_6\) incubated on ice; **lane 3:** Cy5-\(P_{mtlA}\) and MtlR-His\(_6\) incubated at RT.

To enhance the intensity of the Cy5-\(P_{mtlA}\) shifted band, electrophoretic mobility shift of Cy5-\(P_{mtlA}\) was repeated in shift buffer B (238) (Fig. 3.36.A). In comparison with shift buffer A, shift buffer B lacked EDTA and MgCl\(_2\). Moreover, the pH of the shift buffer B was also 7.5. The results indicated no significant difference between shift buffer A and B. Altogether, changing the shift buffer, incubation temperature and MtlR-His\(_6\) concentration did not improve the mobility shift reaction. Therefore, the crude extract of strain KM12 pKAM39 was considered in order to investigate whether the MtlR-His\(_6\) is inactivated during the purification process. For this purpose, the crude extract of strain KM12 pKAM39 was added to Cy5-\(P_{mtlA}\) DNA, rather than purified MtlR-His\(_6\). In this case, a weak Cy5-\(P_{mtlA}\) shifted band was obtained in the presence of KM12 pKAM39 crude extract (Fig. 3.36.B).
Results

Fig. 3. 36. (A) Electrophoretic mobility shift of Cy5-P_{mtlA} DNA fragment by the purified MtlR-His\textsubscript{6} using shift buffer B. Lane 1: Cy5-P_{mtlA} (50 fmol); lane 2: Cy5-P_{mtlA} (50 fmol) and MtlR-His\textsubscript{6} (25 ng); lane 3: Cy5-P_{mtlA} (50 fmol) and MtlR-His\textsubscript{6} (51 ng). (B) Electrophoretic mobility shift of Cy5-P_{mtlA} (50 fmol) by 2 \mu l of KM12 pKAM39 crude extract. KM12 pKAM39 was incubated overnight at 25\textdegree C in LB. The cells were concentrated (OD\textsubscript{600} of 36) and disrupted by high pressure homogenizer as explained in methods. Shift buffer B was added in a total reaction volume of 10 \mu l. Lane 1: Cy5-P_{mtlA}; Lane 2: Cy5-P_{mtlA} and crude extract.

To confirm the specificity of the observed shifted band by the crude extract, a hybrid promoter was constructed in which the MtlR binding site of P_{mtlA} was replaced with ManR binding site of P_{manP}. Oligonucleotides s6504 and s6505 were used to amplify the ManR binding site of P_{manP} from the chromosomal DNA of B. subtilis 168 by PCR. Also, the P_{mtlA} core elements were amplified from the B. subtilis 168 chromosomal DNA by PCR using oligonucleotides s6506 and s6507. Next, oligonucleotides s6504/s6507 were applied in a fusion PCR using amplified ManR binding site and P_{mtlA} core elements as the templates. The final P_{manP}-P_{mtlA} fragment (called P_{HP7}) was inserted into pSUN279.2 via NheI/AflII (pKAM21). Using pKAM21 as a template, the Cy5-P_{HP7} fragment was amplified by oligonucleotides s6504 and 5’-Cy5-labeled s5959 in a PCR (Fig. 3.37.A). Electrophoretic mobility shift of Cy5-P_{mtlA} DNA was carried out using the crude extract of KM12 pKAM39, while Cy5-P_{HP7} DNA was a negative control. The addition of KM12 pKAM39 crude extract weakly shifted the Cy5-P_{mtlA} band, whereas no Cy5-P_{HP7} shifted band was observed (Fig. 3.37.B). Therefore, the reduced mobility of Cy5-P_{mtlA} band was obviously due
to the presence of MtlR-His<sub>6</sub> in the crude extract. In summary, the expression of mtlR-His<sub>6</sub> in KM12 strain resulted in a weak shift of Cy5-<i>P</i><sub>mtlA</sub> band using purified MtlR-His<sub>6</sub> or crude extract of KM12 pKAM39. Consequently, the overproduced MtlR-His<sub>6</sub> in KM12 was not fully active which could be due to the presence of a His<sub>6</sub>-tag at the C-terminus of MtlR. Alternatively, the phosphoryl bonds of the phosphorylated histidines in PRDII of MtlR could be labile. To overcome the latter obstacle, MtlR-H342D-His<sub>6</sub> mutant was overproduced in <i>B. subtilis</i> KM12.

The low intensity of the shifted Cy5-<i>P</i><sub>mtlA</sub> band in the presence of the purified MtlR-His<sub>6</sub> or crude extract of KM12 pKAM39 indicated a weak activity of the activator protein. It was assumed that the phosphate covalently bound to histidine 342 at PRDII of MtlR was labile. Therefore, the histidine 342 was mutated to an aspartic acid which is a phosphoryl histidine mimic as shown by <i>in vivo</i> studies (section 3.13.3). By this means, the probable inactivation of the MtlR due to dephosphorylation of PRDII during the purification process was prevented. His 342 was mutated to aspartic acid by oligonucleotides s6686/s6865 and s6866/s6687 in PCRs using the chromosomal DNA of <i>B. subtilis</i> 168 as a template. The primary PCR products were
then used in a fusion PCR by oligonucleotides s6686/s6687. The final PCR product, *mtlR-H342D-His*₆ DNA, was then inserted into pKAM12 using *Afl* III and *Xma*I restriction sites (plasmid pKAM93). After transformation of KM12 by pKAM93, the crude extract of the KM12 pKAM93 was used in an electrophoretic mobility shift assay. The Cy5-*P₇αmtlA* DNA was clearly shifted in the presence of the KM12 pKAM93 crude extract, while Cy5-*P₇HP7* DNA was not shifted (Fig. 3.38).

![Fig. 3.38. Electrophoretic mobility shift of 50 fmol of Cy5-*P₇HP7* DNA (negative control) and 50 fmol of Cy5-*P₇αmtlA* DNA (sample) using cleared crude extract of KM12 pKAM93. The KM12 pKAM93 producing MtlR-H342D-His₆ was cultivated at 25°C and the bacterial culture was harvested after an overnight incubation. The disruption of KM12 pKAM93 (OD₆₀₀ of 17.5) was accomplished by the high pressure homogenizer and the cleared crude extract was used for electrophoretic shift studies. Shift buffer B was used in this study. Lane 1: Cy5-*P₇HP7*; lane 2: Cy5-*P₇αmtlA* and cleared crude extract; lane 3: Cy5-*P₇αmtlA*; lane 4: Cy5-*P₇αmtlA* and cleared crude extract.](image)

Afterwards, the overexpressed MtlR-H342D-His₆ protein was purified by Ni-NTA column. Similar to the experiment with MtlR-His₆, only a low amount of Cy5-*P₇αmtlA* DNA was shifted by the purified MtlR-H342D-His₆ protein. Addition of MgCl₂ (shift buffer C), changing the purification buffer from NaH₂PO₄ pH 8 (affinity chromatography buffer 1) to HEPES pH 7.4 (affinity chromatography buffer 2), as well as addition of the protease inhibitor and β-mercaptoethanol could not improve the binding of MtlR-H342D-His₆ to the DNA (data not shown). Obviously, the MtlR-H342D-His₆ protein was active in the crude extract, but not after purification. Hence, the fusion of His₆-tag had no influence on the MtlR activity. It was assumed that the purification by Ni-NTA column damaged the MtlR-H342D-His₆ protein maybe due to the oxidation of MtlR, especially cysteine residues. Among them, cysteine 419 plays a vital role for...
the MtlR activity. Therefore, MtlR mutants, i.e. MtlR-H342D and MtlR-H342D C419A, were purified using anion exchange chromatography. Further expression and purification strategies are summarized in table 3.1.

3.14.6.3. Expression of mtlR-H342D C419A in E. coli JW2409-1

In the presence of mannitol, the conserved cysteine 419 located at the EIIB\textsuperscript{Gat} domain of MtlR is dephosphorylated by EIIA\textsuperscript{Mtl}. In vivo studies showed that mutation of the cysteine 419 to alanine caused strong constitutive, but still CCR repressible MtlR activity (107). In vivo, H342D mutation significantly reduced the catabolite repression in MtlR (section 3.13.3). Therefore, both mutations were combined. Due to the mutations, the MtlR-H342D C419A activity should be independent from the phosphorylation. Thus, mtlR-H342D C419A was expressed in E. coli. The cysteine 419 was mutated to alanine in a fusion PCR. Oligonucleotides s7303/s7301 and s7302/s7304 were applied in PCRs using pKAM93 (P_{mtlA}-mtlR-H342D) as a template. The fusion PCR was performed by oligonucleotides s7303/s7304 and the primary PCR products as the template. The amplified mtlR-H342D C419A fragment was then inserted into pJOE6089.4 (see appendices), a plasmid with moderate copy numbers based on pBR322 origin of replication, via AflII/XmaI to construct pKAM182. In pKAM182, the expression of the mtlR-H342D C419A was under the control of rhaP_{BAD}, a rhamnose-inducible promoter in E. coli (84). Next, E. coli JW2409-1 lacking the enzyme I (EI) of the PTS system was transformed with pKAM182. Strain JW2409-1 pKAM182 was cultivated in LB at 37°C, induced by 0.2% L-rhamnose, and incubated overnight. The cells were harvested and resuspended in 20 mM Tris-HCl (pH 8) and disrupted by sonication. Afterwards, crude extract of JW2409-1 pKAM182 was used for electrophoretic mobility shift assay. The results indicated that the crude extract of JW2409-1 pKAM182 is able to shift the Cy5-P_{mtlA} DNA fragment, whereas P_{HP7} DNA fragment (negative control) showed no
mobility shift (Fig. 3.39). Additionally, Cy5-labeled P_{mtlR} as well as P_{mtlR} DNA were also tested. P_{mtlR} was a 5’-shortened P_{mtlR} in which half of the MtlR binding site was removed. Oligonucleotides s5799/s5959 (P_{mtlR}) and s6799/s5959 (P_{mtlR}) were used to amplify the Cy5-labeled DNA fragments by PCR from pKAM18 and pKAM51, respectively. Similar to Cy5-P_{mtlA}, the Cy5-P_{mtlR} band was also shifted in the presence of JW2409-1 pKAM182 crude extract. In contrast, the P_{mtlR} fragment was not shifted (Fig. 3.39).

![Fig. 3.39. Electrophoretic mobility shift assay of Cy5-P_{mtlA} DNA (150 fmol) and Cy5-P_{mtlR} DNA (150 fmol) by 6 µl crude extract of JW2409-1 pKAM182 (10 mg/ml) containing MtlR-H342D C419A. Shift reaction was performed in a total volume of 50 µl harboring shift buffer D. As negative controls, DNA of Cy5-P_{HP7} (150 fmol) and Cy5-P_{mtlK} (150 fmol) were applied. Lane 1: Cy5-P_{HP7}; Lane 2: Cy5-P_{HP7} and crude extract; Lane 3: Cy5-P_{mtlA}; Lane 4: Cy5-P_{mtlA} and crude extract; Lane 5: Cy5-P_{mtlR}; Lane 6: Cy5-P_{mtlR} and crude extract; Lane 7: Cy5-P_{mtlK}; and Lane 8: Cy5-P_{mtlR} and crude extract.](image)

Next, the crude extract of JW2409-1 pKAM182 was used for anion exchange chromatography. None of the collected fractions, however, shifted Cy5-P_{mtlA} or Cy5-P_{mtlR} bands. Mobility shift attempts by changing the purification buffer (Buffer A2 and B2 instead of A1 and B1) and addition of 1 mM tris (2-carboxyethyl) phosphine (TCEP) as a reducing agent also failed. Finally, the expression of mtlR-H342D C419A was done at 30°C. In this case, a protein peak appeared in the flow-through fractions of the anion exchange chromatography diagram. This peak was not observed when the cells were cultivated and induced at 37°C. Next, all fractions obtained by
anion exchange chromatography were used in electrophoretic mobility shift assays using Cy5-P$_{mtlA}$ DNA (Fig. 3.40). Interestingly, the Cy5-P$_{mtlA}$ band was shifted by the flow-through fractions. SDS- PAGE analysis showed an almost purified band in the flow-through fractions corresponding to 78 kDa (Fig. 3.41.A). Fraction 3 was used for further studies.

![Fig. 3. 40. Electrophoretic mobility shift of Cy5-P$_{mtlA}$ DNA by the fractions obtained by anion exchange chromatography of JW2409-1 pAM182 crude extract. Strain JW2409-1 pKAM182 expressing mtlR-H342D C419A was induced by 0.2% L-rhamnose. The cells were incubated at 30°C overnight. Anion exchange chromatography was performed by buffers A$_2$ and B$_2$. 20 µl of each fraction (fractions 2 – 67) was added to 200 fmol Cy5-P$_{mtlA}$ DNA fragment. The reaction was performed in a total volume of 50 µl using shift buffer D. The fractions 2 – 67 are represented by the numbers on top of each lane, while shifted band is demonstrated by an arrow.]

Next, Cy5-labeled P$_{HP7}$, P$_{mtlA}$, ‘P$_{mtlR}$, and P$_{mtlR}$ DNA fragments were used in an electrophoretic mobility shift assay using purified MtlR-H342D C419A (fraction 3). The results indicated a clear shift of the Cy5-P$_{mtlA}$ and Cy5-P$_{mtlR}$ bands, whereas no shift was observed for the Cy5-P$_{HP7}$ and Cy5-‘P$_{mtlR}$ bands as negative controls (Fig. 3.41.B). Next, several concentrations of the purified MtlR-H342D C419A were used in order to determine the lowest amount of MtlR-H342D C419A necessary for the complete shift of Cy5-P$_{mtlA}$ band. It was shown that at least 390 ng of MtlR-H342D C419A corresponding to 4.95 pmol was necessary for a complete shift of 100 fmol Cy5-P$_{mtlA}$ fragment (Fig. 3.42.A). Likewise, non-labeled P$_{mtlA}$ was amplified by PCR using oligonucleotides s5526/s5527 from the genome of B. subtilis 168. Addition of the amplified unlabeled P$_{mtlA}$ DNA inhibited the shift of Cy5-P$_{mtlA}$ band (Fig. 3.42.B).
Results

Fig. 3. 41. (A) SDS-PAGE analysis (8% gel) of the early fractions of anion exchange chromatography of crude extract of strain JW2409-1 pKAM182. Fractions 2 – 9 are represented on top of each lane, while L demonstrates the unstained protein molecular weight marker (Fermentas). (B) Electrophoretic mobility shift of DNA containing Cy5-P_H7 (100 fmol), Cy5-P_mtlA (100 fmol), Cy5'-P_mtlR (100 fmol), and Cy5-P_mtlR (100 fmol) by purified MtlR-H342D C419A (23 µl, 130 ng/ml). The reaction was performed in a total volume of 50 µl using shift buffer D. Lane 1: Cy5-P_H7; lane 2: Cy5- P_H7 and MtlR-H342D C419A; lane 3: Cy5-P_mtlA and MtlR-H342D C419A; lane 5: Cy5'-P_mtlR; lane 6: Cy5'-P_mtlR and MtlR-H342D C419A; lane 7: Cy5-P_mtlR; lane 8: Cy5-P_mtlR and MtlR-H342D C419A.

Fig. 3. 42. (A) Electrophoretic mobility shift of Cy5-labeled P_mtlA DNA fragment by purified MtlR-H342D C419A. 100 fmol of Cy5-P_mtlA DNA was mixed with different concentrations of purified MtlR-H342D C419A, namely 780 ng (lane 1), 650 ng (lane 2), 520 ng (lane 3), 390 ng (lane 4), 260 ng (lane 5), 130 ng (lane 6), and without MtlR-H342D C419A (lane 7). (B) Electrophoretic mobility shift of Cy5-P_mtlA DNA (100 fmol) in the presence of unlabeled P_mtlA fragment as a competitor. Unlabeled P_mtlA DNA was added with the concentrations 0 pmol (lane 1), 2 pmol (lane 2), 4 pmol (lane 3), 6 pmol (lane 4). As a control, no MtlR-H342D C419A was added to the Cy5-P_mtlA fragment (lane 5). MtlR-H342D C419A was added to the reaction after mixing the Cy5-labeled P_mtlA and unlabeled P_mtlA DNA fragments. All of the reactions were carried out in a total volume of 50 µl using shift buffer D.
3.14.7. Function of the $P_{mlA}$ and $P_{mlR}$ cre sites and their mutants

Catabolite responsive element (cre) is the binding site of the CcpA-HPr(S46-P) complex. Analyses of the $P_{mlA}$ and $P_{mlR}$ sequences revealed putative cre sites overlapping their -10 boxes. The function of these cre sites was investigated by mutation of their sequences. As demonstrated in Fig. 3.43, each of the cre sites of $P_{mlA}$ and $P_{mlR}$ comprise 3 mismatches compared with the consensus cre sequence. Thus, the cre sites of $P_{mlA}$ and $P_{mlR}$ were first of all mutated to repair the mismatches and construct perfect cre sites ($P_{mlA\ cre^+}$ and $P_{mlR\ cre^+}$; Fig. 3.43). $P_{mlA\ cre^+}$ was constructed by PCRs from B. subtilis 168 genome using oligonucleotides s6209/s6654 and s6655/s6213. Next, a fusion PCR was carried out by the primary PCR products and oligonucleotides s6209/s6213. The $P_{mlA\ cre^+}$ fragment was finally inserted into pSUN279.2 via NheI/AflII (pKAM31). Similarly, $P_{mlR\ cre^+}$ was generated by PCRs from the chromosome of B. subtilis 168 using oligonucleotides s5799/s6664 and s6665/s6392. Afterwards, the primary PCR products were used in a fusion PCR by oligonucleotides s5799/s6392. The $P_{mlR\ cre^+}$ fragment was inserted into pSUN279.2 through NheI/AflII restriction sites (pKAM33). Unexpectedly, strains 3NA pKAM31 ($P_{mlA\ cre^+}$) and 3NA pKAM33 ($P_{mlR\ cre^+}$) indicated low β-galactosidase activity. Strain 3NA pKAM31 showed about 21 Miller units, while strain 3NA pKAM33 produced only 4 Miller units β-galactosidase activity. Besides, $P_{mlA\ cre^+}$ and $P_{mlR\ cre^+}$ were not inducible. It was likely that the mutation of the mismatches located at the Pribnow box of $P_{mlA}$ and $P_{mlR}$ led to such a deficiency.
Fig. 3. Consensus sequences of cre sites including group A and B, the cre sequences of PmtlA and PmtlR, and mutants thereof. Mismatches to consensus sequence are represented by bold letters. Mutations in the sequence of the promoters (-10 box and spacer sequence) are enclosed by rectangles. Improvements of the cre sites of PmtlA and PmtlR into the consensus query are PmtlA cre+ (pKAM31) and PmtlR cre+ (pKAM33), while the disruptions are PmtlA cre- (pKAM32) and PmtlR cre- (pKAM34). N: any base; W: A or T; R: A or G; Y: C or T.

Afterwards, the position of the mutated cre sites was changed in order to facilitate the base pair exchanges without affecting -10 boxes. At first, the cre sites of PmtlA and PmtlR were completely placed in the spacer sequence of PmtlA and PmtlR (Fig. 3.44). The new promoters, denoted PmtlA cre *(−35 and −10) and PmtlR cre *(−35 and −10), were constructed by fusion PCRs. PCRs from B. subtilis 168 genomic DNA was carried out using oligonucleotides s6209/s6709 and s6710/s6213 (PmtlA cre *(−35 and −10)). The final PCR was accomplished by primary PCR products and oligonucleotides s6209/s6213. Similarly, PCRs from the chromosome of B. subtilis 168 were performed by oligonucleotides s5799/s6711 and s6712/s6392. Next, PmtlR cre *(−35 and −10) was generated by final PCR using primary PCR products and oligonucleotides s5799/s6392. Plasmids pKAM40 (PmtlA cre *(−35 and −10)) and pKAM41 (PmtlR cre *(−35 and −10)) were constructed by the insertion of the amplified fragments into pSUN279.2 via NheI/AflII. Strain 3NA pKAM40 showed approximately 300 Miller units β-galactosidase activity, whereas 3NA pKAM41 had expressed only 20 Miller units β-galactosidase activity. Moreover, both of the promoters were no longer inducible.
Results

Fig. 3.44. Adaptation of the spacer sequence between -35 and -10 in \( P_{\text{mtlA}} \) and \( P_{\text{mtlR}} \) to the \( \text{cre} \) consensus sequence and new positioning the newly generated \( \text{cre} \) sequence. The spacer sequence of \( P_{\text{mtlA}} \) (pKAM12), \( P_{\text{mtlA} \cre+} \) (pKAM31), and \( P_{\text{mtlA} \cre-}\) (pKAM40), as well as the spacer sequence of \( P_{\text{mtlR}} \) (pKAM18), \( P_{\text{mtlR} \cre+} \) (pKAM33), and \( P_{\text{mtlR} \cre-}\) (pKAM41) are demonstrated. Plasmids pKAM12 and pKAM18 showed the wild type \( \text{cre} \) sites, whereas pKAM31 and pKAM33 contained the improved \( \text{cre} \) sites. In pKAM40 and pKAM41, the improved \( \text{cre} \) sites were resided exactly between -35 and -10 boxes without overlapping -10 boxes in \( P_{\text{mtlA}} \) and \( P_{\text{mtlR}} \).

In addition, the \( \text{cre} \) sites of \( P_{\text{mtlA}} \) and \( P_{\text{mtlR}} \) were mutated to disrupt the binding of the CcpA-HPr(S46~P) complex. Disruption of the \( \text{cre} \) site of \( P_{\text{mtlA}} \) was accomplished using oligonucleotides s6209/s6656 and s6657/s6213 in PCRs from the \( B. \text{subtilis} \) chromosomal DNA. The \( P_{\text{mtlA} \cre-} \) fragment was generated by a fusion PCR using the primary PCR products and oligonucleotides s6209/s6213. Likewise, the \( \text{cre} \) site of \( P_{\text{mtlR}} \) was mutated. Oligonucleotides s5799/s6666 and s6667/s6392 were used for PCRs from the genomic DNA of \( B. \text{subtilis} \) 168. By a fusion PCR using the primary PCR products and oligonucleotides s5799/s6392, \( P_{\text{mtlR} \cre-} \) was generated. Insertion of \( P_{\text{mtlA} \cre-} \) and \( P_{\text{mtlR} \cre-} \) into pSUN279.2 was performed via NheI/AflII to construct pKAM32 and pKAM34, respectively. \( \beta \)-galactosidase activities of 3NA pKAM32 and 3NA pKAM34 were measured after cultivation in LB (Fig. 3.45.A and Fig. 3.45.B). For induction, mannitol (0.2%) was added with or without 0.2% glucose to the bacterial culture. Interestingly, \( \beta \)-galactosidase activity of 3NA pKAM32 (\( P_{\text{mtlA} \cre-} \)) was identical to 3NA pKAM12. Strain 3NA pKAM34 (\( P_{\text{mtlR} \cre-} \)) exhibited a higher \( \beta \)-galactosidase activity (135 Miller units) in comparison to 3NA pKAM18. The addition of glucose to the induced 3NA pKAM34 culture reduced the \( \beta \)-galactosidase activity to 39 Miller units, while this amount was only about 19 Miller units in 3NA pKAM18. Due to a higher maximal activity of \( P_{\text{mtlR} \cre-} \), it cannot be concluded that the \( P_{\text{mtlR}} \) \( \text{cre} \) site in the wild type strain is functional.
Results

Fig. 3.45. Disruption of the *cre* sites of \( P_{mtlA} \) and \( P_{mtlR} \). (A) \( \beta \)-galactosidase activity of 3NA pKAM12 (\( P_{mtlA} \)) and 3NA pKAM32 (\( P_{mtlA \ cre} \)) is shown. (B) \( \beta \)-galactosidase activity of 3NA pKAM18 (\( P_{mtlR} \)) was compared to 3NA pKAM34 (\( P_{mtlR \ cre} \)).

3.14.8. Fusion of \( P_{groE} \) to *cre* sites

Mutation of the *cre* sites overlapping -10 box as well as new positioning of the *cre* sites significantly affected the \( P_{mtlA} \) and \( P_{mtlR} \) activities. Besides, expression of *mtlR* in the genome of *B. subtilis* could interfere with the obtained results due to the presence of a potential *cre* site in \( P_{mtlR} \). Therefore, a constitutive promoter was used which was neither influenced by the CcpA-dependent CCR nor MtR transcription activation. The promoter of the *groELS* operon (\( P_{groE} \)) encoding the large and small subunits of GroEL chaperone is negatively regulated by a protein called HrcA (193, 197). The binding site of the HrcA is located at the UTR of the *groEL* mRNA; therefore, deletion of the mRNA leader sequence of \( P_{groE} \) resulted in a strong constitutive promoter activity. Therefore, this strong promoter activity might be blocked by the presence of a *cre* site located at the +1 of the UTR sequence in a road block mechanism. By using \( P_{groE} \) core elements, the function of the *cre* sites of \( P_{mtlA} \) and \( P_{mtlR} \) were compared to the already studied *cre* site of \( P_{acsA} \). The *acsA* encoding an acetyl-CoA synthetase is regulated by the CcpA-dependent catabolite repression (80, 262). Additionally, there is another reported *cre* site located inside the coding frame of *mtlA* (44). This *cre* site, denoted *cremtlA*, was also studied. The UTR of \( P_{mtlR\ lacZ} \) on pKAM18 was fused to \( P_{groE} \) core elements (Fig. 3.46A).
A

**Fig. 3.** Function of the cre sites of $P_{mtlA}$, $P_{mtlR}$, $P_{acsa}$, and $mtlA$. (A) Fusion of the cre sites of $P_{mtlA}$ (pKAM88), $P_{mtlR}$ (pKAM89), $P_{acsa}$ (pKAM90), and internal cre site of $mtlA$ (pKAM91) to $P_{groE}$ and $UTR_{mtlR}$. The construct pKAM101 shows the direct fusion of untranslated region of $P_{mtlR}$ ($UTR_{mtlR}$) to the $P_{groE}$. (B) β-galactosidase activity of strain 3NA harboring pKAM88, pKAM89, pKAM90, pKAM91, and pKAM101 in the presence of 0.2% glucose or 0.2% xylose. No sugar was added to the control. The cells were cultivated in LB at 37°C and the sugars were added at the OD$_{600}$ of 0.4. β-galactosidase activity was measured 1 h after the addition of the sugars.

PCR were performed by oligonucleotides s7098/s7189 and s7190/s6392 using genomic DNA of *B. subtilis* 168 as a template. $P_{groE}$-cre$P_{mtlA}$ fragment was generated by fusion PCR using...
Results

Oligonucleotides s7098/s6392 and the primary PCR product. Similarly, oligonucleotides s7098/s7191 and s7192/s6392 (P\textsubscript{groE-cre}\textsubscript{pm1R}), s7098/s7193 and s7194/s6392 (P\textsubscript{groE-cre}\textsubscript{pacsA}), and s7098/s7195 and s7196/s6392 (P\textsubscript{groE-cre}\textsubscript{mt1A}) were used for PCRs from the chromosome of \textit{B. subtilis} 168. The final \textit{P\textsubscript{groE-cre-UTR}\textsubscript{mt1R}} fusions were generated by oligonucleotides s7098/s6392 and the primary PCR products. As a negative control, \textit{P\textsubscript{groE}} was directly fused to the UTR\textsubscript{mt1R}. Oligonucleotides s7098/s7237 and s7238/s6392 were used for PCRs from \textit{B. subtilis} 168 chromosomal DNA. The \textit{P\textsubscript{groE-UTR}\textsubscript{mt1R}} fragment was amplified in a fusion PCR by oligonucleotides s7098/s6392 and the primary PCRs products. All of the \textit{P\textsubscript{groE-cre-UTR}\textsubscript{mt1R}} fragments were then inserted into pSUN279.2 via NheI/AflII (Fig. 3.46.A). \textbeta-galactosidase activity of strains 3NA pKAM88 (P\textsubscript{groE-cre}\textsubscript{pm1A}), 3NA pKAM89 (P\textsubscript{groE-cre}\textsubscript{pm1R}), 3NA pKAM90 (P\textsubscript{groE-cre}\textsubscript{pacsA}), and 3NA pKAM91 (P\textsubscript{groE-cre}\textsubscript{mt1A}) were compared to 3NA pKAM101 (P\textsubscript{groE-UTR}\textsubscript{mt1R}) in the presence of xylose or glucose in LB (Fig. 3.46.B). The results indicated that \textit{cre}\textsubscript{pm1A} on pKAM88 and \textit{cre}\textsubscript{pm1R} on pKAM89 could reduce the \textit{P\textsubscript{groE}} activity by 1.5- and 1.7-fold in the presence of glucose, while this amount was about 2.8-fold in \textit{P\textsubscript{pacsA}}. Strain 3NA pKAM101, the negative control, showed the same \textbeta-galactosidase activity in LB with or without glucose. Strain 3NA pKAM91 showed a 1.3-fold \textbeta-galactosidase activity reduction in LB with glucose. Therefore, it is assumed that the \textit{mt1A} internal \textit{cre} site has no biological function.

3.15. Expression system based on mannitol regulatory elements

3.15.1. Optimization of -10 box in \textit{P\textsubscript{mt1A}}

The -10 box of \textit{P\textsubscript{mt1A}} was mutated to the \textsigma^A consensus sequence (TATAAT) in order to increase the \textit{P\textsubscript{mt1A}} activity. Basically, isomerization of the dsDNA takes place at -10. Presence of a cytosine residue in the -10 box changes the stacking energies. As a consequence, unwinding of dsDNA and development of an open complex might be negatively affected in \textit{P\textsubscript{mt1A}}. Optimization of the Pribnow box of \textit{P\textsubscript{mt1A}} was carried out by using oligonucleotides s6209/s6713 and s6714/s6213 for PCRs from \textit{B. subtilis} 168 chromosome. In the next step, fusion PCR was accomplished by using oligonucleotides s6209/s6213 and primary PCR products. The \textit{P\textsubscript{mt1A}} fragment comprising an optimized -10 box was then inserted into pSUN279.2 via NheI/AflII to
construct pKAM42.  β-galactosidase activity of 3NA pKAM42 was measured after cultivation in LB with or without mannitol (Fig. 3.47). Induced 3NA pKAM42 gave 11,700 Miller units β-galactosidase activity, whereas the basal β-galactosidase activity was about 2,100 Miller units. The intended optimization of the -10 box tripled the basal activity of \( P_{m1A} \), but maximal activity was about the same as with the induced \( P_{m1A} \). Hence, \( P_{m1A} \) core elements were not altered for further studies.

![Fig. 3.47](image.png)

**Fig. 3.47.** Intended optimization of -10 box of \( P_{m1A} \). The β-galactosidase activity of strain 3NA harboring pKAM12 (\( P_{m1A} \) with wild type -10 box) and pKAM42 (\( P_{m1A} \) with optimized -10 box).

### 3.15.2. Shortening the 5’UTR in \( P_{m1A}\)-lacZ mRNA

It was shown that shortening of the 5’UTR of \( P_{m1A}\)-lacZ mRNA increased the β-galactosidase activity probably by enhancing the translational initiation efficiency (section 3.3). Further shortening of the 5’UTR of \( P_{m1A}\)-lacZ mRNA on pKAM12 was carried out in order to enhance the β-galactosidase production. Interestingly, deletion of the first 10 bp from the 5’UTR of \( P_{m1A}\)-lacZ mRNA on pKAM12 increased the β-galactosidase activity. Oligonucleotides s6209 and s6794 were used to amplify \( P_{m1A} \) from \( B. \) subtilis 168 chromosome. The shortened \( P_{m1A} \) was inserted into pSUN279.2 via \( NheI/AflII \) to create pKAM50 (Fig. 3.48.A). After induction of the 3NA pKAM50, 16,000 Miller units β-galactosidase activity were achieved, while uninduced cells
showed about 800 Miller units (Fig. 3.48.B). Further deletion of the 5’UTR\textsubscript{PmtlA-lacZ} was accomplished by PCR with oligonucleotides s6209/s6727 and the chromosome of \textit{B. subtilis} 168 as template. By insertion of the PCR fragment via \textit{NheI/AflII} into pSUN279.2, pKAM44 was constructed. Unlike 3NA pKAM12 and 3NA pKAM50, 3NA pKAM44 induced cells showed a reduction in β-galactosidase activity. Induced 3NA pKAM44 expressed only 3,500 Miller units β-galactosidase activity. Thus, shortened \textit{PmtlA} on pKAM50 was used for further studies.

![Fig. 3. 48. (A) \textit{PmtlA} on pKAM12 and constructs thereof shortened at the UTR from 3’-end. The first base pair of each shortened \textit{PmtlA} is enclosed by an arrow and a rectangle. (B) β-galactosidase activity of strain 3NA harboring pKAM12, pKAM44 and pKAM50.](image)

\textbf{3.15.3. Construction of expression vectors based on pUB110}

So far, all of the studies on \textit{PmtlA} and \textit{PmtlR} were accomplished based on a low copy replicon, pBS72. In order to construct an expression vector with \textit{PmtlA}, a high copy number vector was employed. Plasmid pMW168.1 was used as the vector backbone (242). This plasmid is a derivative of pUB110 (\textit{ori\textsubscript{pUB110}}) originated from \textit{Staphylococcus aureus} (119). Plasmid pMW168.1 contains a spectinomycin resistant gene originated from \textit{Enterococcus faecalis}, an \textit{ori}\textsuperscript{+} of pUB110, and finally \textit{gsiB} translational initiation region (TIR\textsubscript{gsiB}) fused to eGFP (Fig. 3.49; see appendices). By PCR from genomic DNA of \textit{B. subtilis} 168, \textit{PmtlA} was amplified using oligonucleotides s7355/s7620. Similarly, \textit{PmtlR} was amplified employing oligonucleotides s7621/s7622. The PCR products were next inserted into pMW168.1 via \textit{AgeI/BglII}. In this way,
the \( P_{\text{mtlA}} \) and \( P_{\text{mtlR}} \) core elements were fused to UTR\textsubscript{\textit{manP}} on pMW168.1. Strain 3NA was then transformed with pKAM163 (\( P_{\text{mtlA}} \)) and pKAM164 (\( P_{\text{mtlR}} \)). Afterwards, the fluorescence intensity of the expressed eGFP was measured. The fluorescence intensity of 3NA pKAM163 and 3NA pKAM164 was measured 6 h after addition of mannitol to culture. As a control, strain 3NA pMW168.1 was used in this study.

**Fig. 3. 49.** The sequence of \( P_{\text{manP}} \) on pMW168.1. Restriction sites are underlined. The ManR binding site is highlighted in gray. The Pribnow box is enclosed by a rectangle. The transcription start site (+1) and the ribosomal binding site (RBS) are shown by bold letters. The start codon of the \( \text{gslB-eGFP} \) hybrid protein is represented by bold capital letter. The gene sequences are demonstrated by dashed arrows.

Addition of mannitol to 3NA pKAM163 culture induced the expression of eGFP by 15-fold to about 1005 relative fluorescence units (RFU). The \( P_{\text{mtlA}} \) activity on pKAM163 was significantly lower than \( P_{\text{manP}} \) on pMW168.1 (approx. 3.5- fold). Induced 3NA pKAM164 (\( P_{\text{mtlR}} \)) showed low fluorescence intensity with about 610 RFU, while the uninduced cells had only 394 RFU (Fig. 3.50.A).
3.15.4. Improvement of the expression vector based on $P_{mtlA}$

To optimize the activity of $P_{mtlA}$ on a pUB110 derivative, the $P_{mtlA}$ sequence on pKAM50 with its shortened 5’UTR originating from $mtlA$ was inserted into the pMW168.1 to replace $P_{manP}$ and 5’UTR$_{gsiB}$. The $P_{mtlA}$ fragment was amplified by PCR from pKAM50 using oligonucleotides s7355/s7356. The PCR fragment was inserted into pMW168.1 via AgeI/AflII (pKAM144). Induced 3NA pKAM144 showed a 1.5-fold stronger fluorescence intensity than 3NA pKAM163 with about 1500 RFU (Fig. 3.50.A). Also, basal fluorescence intensity of 3NA pKAM144 was 3-fold higher than 3NA pKAM163. Plasmid pKAM144 lacked a NdeI restriction site at the start codon of the eGFP reporter gene. Therefore, plasmid pKAM114 was constructed in order to generate a NdeI restriction site at the start codon (Fig. 3.50.B).

![A and B diagrams](image-url)

**Fig. 3.50.** (A) Expression of eGFP in *B. subtilis* 3NA by $P_{manP}$ (pMW168.1), $P_{mtlA}$ (pKAM114, pKAM144, pKAM163, and pKAM169), or $P_{mtlR}$ (pKAM164). pKAM163 (contains $P_{mtlA}$-UTR$_{manP}$) and pKAM164 (contains $P_{mtlR}$-UTR$_{manP}$) were constructed by insertion of $P_{mtlA}$ and $P_{mtlR}$ core elements (without their UTR sequence) via AgeI/BglII into pMW168.1. Insertion of $P_{mtlA}$ with its own UTR sequence ($P_{mtlA}$-UTR$_{mtlA}$) via AgeI/AflII into pMW168.1 resulted in pKAM144. Construction of the NdeI site in pKAM144 led to creation of pKAM114. Insertion of $P_{mtlR}$-$mtlR$ into pKAM114 resulted in pKAM169. The bacterial culture was induced by mannose ($P_{manP}$) or mannitol ($P_{mtlA}$) at the OD$_{600}$ of 0.4 and the fluorescence intensity was measured after 6 h. (B) The $P_{mtlA}$ sequence on pKAM114. The restriction sites are underlined. The proposed MtlR binding site is gray highlighted. The Pribnow box and -35 box are enclosed by rectangles. The transcription start site (+1) and the ribosomal binding site (RBS) are shown by bold letters. The start codon of GsiB-eGFP hybrid protein is demonstrated by bold capital letter. The gene sequences are depicted by dashed arrows. Mutations for construction of NdeI restriction site are highlighted in gray.
Oligonucleotide s7355 and s7356 were used in a PCR from pKAM50 to amplify $P_{mtlA}$-TIR$_{gsiB}$ fragment. Oligonucleotide s7356 contained the $gsiB$ ribosomal binding site and the initially translated codons of pMW168.1 as a tail (Fig. 3.49). The $P_{mtlA}$-TIR$_{gsiB}$ fragment was then inserted into pMW168.1 via AgeI/BamHI (Fig. 3.50.B). Strain 3NA pKAM114 produced about 1,711 RFU of eGFP in the presence of mannitol. The induction by mannitol was 16-fold compared to uninduced 3NA pKAM114. Despite the fact that eGFP production increased, the 3NA pKAM114 produced still half of the 3NA pMW168.1 fluorescence intensity (Fig. 3.50.A).

Fig. 3.51. The plasmid map of pKAM114 harboring $P_{mtlA}$ and its derivative pKAM169.

Lower activity of $P_{mtlA}$ on pKAM114 in comparison with $P_{manP}$ on pMW168.1 could be due to the lower amount of its activator in the cell. Comparison of the $P_{manR}$ activity and $P_{mtlR}$ activity on pBS72 derivatives expressing lacZ showed that $P_{manR}$ on pSUN291 (214) was about 22 times stronger than $P_{mtlR}$ on pKAM3. Thus, the single $P_{mtlR}$-mtlR copy on the chromosome might not express enough MtlR to activate $P_{mtlA}$ in all of the pKAM114 copies. To increase the number of MtlR in the cell, the activator gene with its own promoter ($P_{mtlR}$-mtlR) was inserted into pKAM114. The $P_{mtlR}$-mtlR DNA cassette was amplified by PCR from B. subtilis 168 genome using oligonucleotides s5656/s5657. The fragment was then inserted into pJOE4786.1 which was
already cut by SmaI (pKAM01). Plasmid pKAM01 was then cut by BamHI and the overhangs of the 2.3 kb fragment were filled in by Klenow polymerase. Next, pKAM114 was digested by PvuII. By insertion of $P_{mtlR}$-$mtlR$ into pKAM114 DNA, plasmid pKAM169 was obtained. The plasmid map of pKAM114 and pKAM169 are depicted in Fig. 3.51. Induction of 3NA pKAM169 showed boosted fluorescence intensity in comparison with 3NA pKAM114. The fluorescence intensity of induced 3NA pKAM169 was about 3900 RFU which was slightly higher than of 3NA pMW168.1. However, the basal fluorescence intensity of the 3NA pKAM169 was considerably higher than of 3NA pMW168.1 (14-fold). Altogether, the results indicated that increasing the number of low copy MtlR in the cell, increased $P_{mtlA}$ activity. However, high basal activity of $P_{mtlA}$ on pKAM169 makes this expression system less suitable for industrial applications.
4. Discussion

4.1. Structure and transcription activation of P_{mtlA} and P_{mtlR}

In this study, regulation of expression of the mtlAFD operon and its activator encoding gene (mtlR) in *B. subtilis* was investigated. For this purpose, the promoters of mtlAFD (P_{mtlA}) and mtlR (P_{mtlR}) were fused to lacZ. Both of these promoters were highly inducible by mannitol and glucitol. To clarify the structures of P_{mtlA} and P_{mtlR}, their transcription start sites were first identified. Characterization of the transcription start sites of P_{mtlA} and P_{mtlR} indicated that both of these promoters contain conserved -10 and -35 boxes resembling σ^A-type promoter structure. Besides, a 17 bp spacer sequence was located between the -35 and -10 boxes in P_{mtlA} as well as in P_{mtlR}. Previously, P_{manP} and P_{manR} of mannose PTS and P_{licB} and P_{licR} of lichenan PTS, all of which are activated by PRD-containing activators, were also shown to have a σ^A-type structure (214, 221). Transcription initiation at P_{mtlA} and P_{mtlR} is activated by binding of MtlR to the promoters. Prior to this study, a 37 bp MtlR binding site in P_{mtlA} was proposed by Watanabe *et al.* (239) based on the MtlR binding site in *G. stearothermophilus* P_{mtlA} (Fig. 4.1) (94).

![Fig. 4. 1. -35 box and its upstream sequence in G. stearothermophilus P_{mtlA} as well as in B. subtilis P_{mtlA} and P_{mtlR}. The regions identified by DNA footprint are shown by FP1 – FP5 and the sequences are highlighted in black. Similar flanking regions of P_{mtlA} and P_{mtlR} are highlighted in gray. The inverted repeats or direct repeats are shown by arrows.](image)

Here, in order to find the probable MtlR binding site, the upstream sequences of -35 boxes of P_{mtlA} and P_{mtlR} were aligned. Comparison of the P_{mtlA} and P_{mtlR} sequences showed a similar incomplete inverted repeat (TTGNCACAN_4TGTGNCAA) upstream of their -35 boxes (Fig. 3.25). This inverted repeat was encompassed by 11 bp flanking sequences (called distal and...
proximal flanking; highlighted in gray, Fig. 4.1) in \( P_{mlA} \) and \( P_{mliR} \). Interestingly, \( B. \ subtilis \ P_{mlA} \) and \( G. \ stearothermophilus \ P_{mlA} \) shared a palindromic sequence (TTTTTAAAAA, denoted T5A5) at the distal flanking region of \( P_{mlA} \) (gray arrows; Fig. 4.1). Likewise, there is a similar sequence in \( P_{mliR} \), albeit with two mismatches (TTTTTCAATA). In addition to the T5A5 sequence, there is also a direct repeat (TTTTT) at \( P_{mlA} \) shown by doubled arrows in Fig. 4.1. By shortening the \( P_{mlA} \) 5'-end, half of this direct repeat was deleted with no significant influence on the \( P_{mlA} \) activity. In contrast, any deletion in the T5A5 sequence reduced the \( P_{mlA} \) activity (Fig. 3.27). Construction of \( P_{mlA}-P_{licB} \) as well as \( P_{mlA}-P_{manP} \) hybrid promoters revealed the importance of another inverted repeat in \( P_{mlA} \) located adjacent to -35 box (AAAGTN7ACTTT; dashed arrows in Fig. 4.1). At first, it was thought that the palindromic T5A5 sequence forms the boundary of the 5'-end, and the inverted repeat located adjacent to the \( P_{mlA} \) -35 box the boundary of the 3'-end of MtlR binding site (154). However, both of these inverted repeats are AT-rich sequences. Besides, these inverted repeats were similar to the UP element subsites including consensus proximal subsite (5’–AAAAAARNR–3’) and distal subsite (5’–AWWWWWTWT–3’) sequences (55). Practically, any deletion or disruption in these sequences only reduced the level of \( P_{mlA} \) activity, while \( P_{mlA} \) remained highly inducible (Fig. 3.27). Therefore, these repeats might be the distal and proximal subsites of an UP element, where \( \alpha \)CTDs of the RNA polymerase bind. Similar inverted repeats were found in \( P_{mliR} \), albeit shorter or disrupted. Unlike the putative subsites of the UP element, any disruption in the incomplete inverted repeat (TTGNCACAN4TGTGNCAA) located between flanking regions (highlighted in gray; Fig. 4.1) rendered \( P_{mlA} \) nearly inactive and no further inducible; therefore, this inverted repeat is likely the MtlR binding site (Fig. 3.27). The location of the MtlR binding site and its interaction with \( \alpha \)CTD is similar to the promoters activated by class I mechanism. Basically, location of the binding sites of class I activators is variable due to the flexibility of the linker between \( \alpha \)CTD and \( \alpha \)NTD. In contrast, the binding location of class II activators cannot be varied because of constraints in the location of \( \sigma \) domain 4 (10). Indeed, increasing the distance between MtlR binding site and -35 box considerably reduced the activity of \( P_{mlA} \); however, the \( P_{mlA} \) remained inducible (Fig. 3.31.A). This shows the flexibility of the location of MtlR binding site in \( P_{mlA} \). Accordingly, a class I activation is proposed for \( P_{mlA} \) and \( P_{mliR} \), where MtlR binds adjacent to the \( \alpha \)CTD monomers of RNA polymerase and its binding site has no overlap with -35 box. Unlike \( B. \ subtilis \) MtlR, it seems
that other DeoR-type PRD-containing activator, *B. subtilis* ManR, assemble a class II activation complex during the transcription initiation. The ManR binding site overlaps -35 box in *P*\textsubscript{manP} as shown by construction of *P*\textsubscript{manP}-*P*\textsubscript{mtlA} hybrid promoters (section 3.14.5.1). In this case, *P*\textsubscript{manP} is activated by a class II mechanism.

*In vitro* studies were carried out to demonstrate the interaction between the putative MtlR binding site and MtlR. Previously, *B. subtilis* MtlR-His\textsubscript{6} and *G. stearothermophilus* MtlR-His\textsubscript{6} were produced and purified from *E. coli* and used for electrophoretic mobility shift (94, 239). However, only the MtlR binding site in *G. stearothermophilus* has been so far identified using DNase I footprinting assay (94). Unlike previous attempts, production of MtlR-His\textsubscript{6} or MtlR-H342D-His\textsubscript{6} in *B. subtilis* or *E. coli* failed in this study. Similar negative results were obtained producing ManR-His\textsubscript{6} in *E. coli* (213). It is assumed that the presence of Ni\textsuperscript{2+} oxidizes the cysteine residues in MtlR, especially the one which is located at the EIIB\textsuperscript{Gal}-like domain. This cysteine plays an important role in the activity of MtlR (see below). Therefore, a MtlR double mutant, MtlR-H342D C419A was produced in *E. coli* JM109 and purified using ion exchange chromatography. Surprisingly, the produced MtlR-H342D C419A in *E. coli* JM109 was inactive, even in the crude extract. An explanation would be that the PRDI domain of PRD-containing regulators might be phosphorylated by HPr(H15~P) in *E. coli*. Perhaps, this phosphorylation deactivates MtlR-H342D C419A in *E. coli*. Phosphorylation of PRDI was shown by Bahr *et al.* (8) when they expressed *licT* in *E. coli*. Thus, an *E. coli* strain was used in which the EI was deleted (Δ*ptsI*). The active form of purified MtlR-H342D C419A was obtained only by cultivation of *E. coli* Δ*ptsI* at 30°C. Surprisingly, the functional protein did not bind to the matrix of an anion exchange chromatography column at pH 7.4, although the predicted pI of MtlR was about 5. Nevertheless, electrophoretic mobility shift assays showed that MtlR-H342D C419A interacts with *P*\textsubscript{mtlA} and *P*\textsubscript{mtlR} DNA fragments *in vitro*. Further experiments are necessary to optimize the DNase I footprinting assay.

Preliminary studies showed that *P*\textsubscript{mtlA} has a higher maximal activity than *P*\textsubscript{mtlR} (4.5-fold; sections 3.1 and 3.5). However, the *P*\textsubscript{mtlR} core elements were more similar to the σ\textsuperscript{A}-type promoter consensus sequence than the corresponding elements of *P*\textsubscript{mtlA}. This effect could be due to a different promoter strength or different translation initiation efficiency. To exclude the effect
of translation initiation efficiency on the promoter activity, the promoter core elements and -35 upstream sequence of $P_{mtlA}$ and $P_{mtlR}$ were fused to the same 5’UTR originating from $manP$ (section 3.15.4). In this way, the maximal activity of $P_{mtlA}$ (producing 1005 R.F.U.) was only 1.6-fold stronger than $P_{mtlR}$ (producing 610 R.F.U.). Likewise, fusion of $P_{mtlR}$ to the 5’UTR of $mtlA$ dramatically increased the $P_{mtlR}$ maximal activity (Fig. 3.9). Thus, it is assumed that the high level of difference between $P_{mtlA}$ and $P_{mtlR}$ activities in the preliminary studies was mainly due to the translational initiation efficiency. Likewise, the $P_{mtlA}$-UTR$_{manP}$ and $P_{mtlR}$-UTR$_{manP}$ fusions revealed that $P_{mtlR}$ is only induced by 1.5-fold, while $P_{mtlA}$ is inducible by 15-fold (compare 3NA pKAM163 to 3NA pKAM164; Fig. 3.50). Similar results were obtained by $P_{mtlR}$-UTR$_{mtlA}$ (Fig. 3.9). In fact, the higher induction rate of $P_{mtlA}$ could be due to the upstream region of its -35 box containing MtlR binding site and putative UP elements. Experimentally, the $P_{mtlR}$ activity was doubled by exchanging its upstream region of -35 box with the $P_{mtlA}$ counterparts (Fig. 3.26.B). Accordingly, it is probable that $P_{mtlR}$ has a good match to $\sigma^A$-type promoter core elements; therefore, this may make the transcription initiation of $P_{mtlR}$ less dependent to the activator MtlR. This mechanism is vice versa in $P_{mtlA}$, where $P_{mtlA}$ lacks a good match to $\sigma^A$-type promoter core elements and requires MtlR activator.

4.2. Regulation of $P_{mtlA}$ and $P_{mtlR}$

The activities of $P_{mtlA}$ and $P_{mtlR}$ were studied in the $B. subtilis$ mutants in which the $mtlAFD$ operon structural genes or the $mtlR$ gene were deleted or disrupted. First, the influence of the mannitol-specific PTS transporter was studied by deletion of the $mtlAF$ genes. Loss of both EIICB$^{Mtl}$ and EIIA$^{Mtl}$ transporter components resulted in constitutive activities of $P_{mtlA}$ and $P_{mtlR}$, although catabolite repression remained functional (Fig. 3.11 and Fig. 3.12). The activities of $P_{levD}$, $P_{manP}$ and $P_{manR}$ are also constitutive when their cognate specific PTS transporter were disrupted or deleted in $B. subtilis$ (145, 214). Similar to the $\Delta mtlAF$ mutant, $P_{mtlA}$ and $P_{mtlR}$ activities were constitutive and glucose-repressible in the $\Delta mtlF$ mutant (deletion of EIIA$^{Mtl}$) as well as in the $\Delta mtlAFD$ mutant. Thus, $B. subtilis$ MtlR is negatively influenced by phosphorylation from EIICB$^{Mtl}$ and EIIA$^{Mtl}$ in the absence of mannitol similar to $G. stearothermophilus$ MtlR (93). Unexpectedly, the maximal activities of $P_{mtlA}$ and $P_{mtlR}$ in
Discussion

*B. subtilis* ΔmtlF, ΔmtlAF, and ΔmtlAFD were considerably different. The *P*<sub>mtlA</sub> maximal activity in the ΔmtlAF mutant was the same as with induced wild type strain (producing 13,000 – 14,000 Miller units β-galactosidase). In contrast, the *P*<sub>mtlA</sub> maximal activity in the ΔmtlF mutant (producing 24,000 Miller units β-galactosidase) was higher than in the ΔmtlAF mutant. On the other hand, *P*<sub>mtlA</sub> maximal activity in ΔmtlAFD (producing 1,200 Miller units β-galactosidase) was considerably lower than in the ΔmtlAF mutant. Similar results were obtained by Deutscher et al. (personal communication) when they integrated the *P*<sub>mtlA</sub>-lacZ into the chromosome. The cytoplasmic phosphocarrier protein EIIA<sup>Mtl</sup> (encoded by *mtlF*) transfers the phosphoryl group from HPr(H15~P) to the domain B of membrane-bound EIICB<sup>Mtl</sup>. Therefore, in the absence of EIIA<sup>Mtl</sup>, the membrane-bound EIICB<sup>Mtl</sup> remains unphosphorylated. Maybe, the presence of the domain B of EIICB<sup>Mtl</sup> has a positive regulatory effect on MtlR activity when the cytoplasmic phosphocarrier EII<sup>Mtl</sup> is absent. This assumption was strengthened by the fact that expression of the domain B of EIICB<sup>Mtl</sup>, fused to another membrane protein, restored the high constitutive activity of *P*<sub>mtlA</sub> in the mutant which lacks both EIIA<sup>Mtl</sup> and EIIB<sup>Mtl</sup> (Deutscher et al.; unpublished). Nevertheless, it does not explain the high activity of *P*<sub>mtlA</sub> in the ΔmtlF mutant, and its low activity in ΔmtlAFD. The difference could also be due to the presence and absence of *mtlD*, encoding the mannitol 1-phosphate dehydrogenase. However, *mtlD* disruption or deletion (data not shown) led to the same *P*<sub>mtlA</sub> maximal activity as in wild type strain, although the basal activity of *P*<sub>mtlA</sub> was slightly increased. The *P*<sub>mtlR</sub> activity obtained in the ΔmtlD mutant was also comparable to *P*<sub>mtlA</sub> in the ΔmtlD mutant. Interestingly, by studying the genome of *B. subtilis*, an antisense RNA in the sequence of *mtlD* was predicted (103). The presence of an antisense RNA could also have a regulatory effect on expression of the *mtlAFD* and *mtlR* genes. But, deletion of the *mtlD* gene had no effect on the *P*<sub>mtlA</sub> activity (data not shown). Thus, it is unlikely that the different *P*<sub>mtlA</sub> activities in the *mtl* mutants are due to antisense RNA. Until now, there is no explanation for the different levels of *P*<sub>mtlA</sub> activities in the ΔmtlAF, ΔmtlF, and ΔmtlAFD mutants.

Altogether, the results are in line with a recent publication revealing the phosphorylation of MtlR EII-like domains by EIICB<sup>Mtl</sup> and EIIA<sup>Mtl</sup> (107). *In vivo* and *in vitro* studies indicated that histidine 599, located at EIIA<sup>Mtl</sup>-like domain of MtlR, is phosphorylated by domain B of
EIICB\textsuperscript{Mtl} in the absence of mannitol. Likewise, cysteine 419 in EIIB\textsuperscript{Gat}-like domain of MtlR is phosphorylated by cytoplasmic phosphocarrier EIIA\textsuperscript{Mtl}. Site-specific mutation of the histidine 599 to alanine of MtlR protein rendered \( P_{\text{mtlA}} \) partially constitutive with only 30% of the \( P_{\text{mtlA}} \) maximal activity in the wild type strain when mannitol was added to the bacterial culture. In contrast, \( P_{\text{mtlA}} \) indicated a strong constitutive activity in the \( mtlR\)-C419A mutant strain (107). Deletion of the EIIB\textsuperscript{Gat}-like and EIIA\textsuperscript{Mtl}-like domains of ManR likewise rendered \( P_{\text{manP}} \) constitutive (213). Therefore, phosphorylation of the domains EIIB\textsuperscript{Gat}-like (containing C419) and EIIA\textsuperscript{Mtl} (harboring H599) inactivates MtlR in the absence of mannitol. In the presence of mannitol, the dephosphorylation of these domains by the mannitol PTS transporter components results in a constitutive activity of MtlR (as also shown in this study) (107). Apparently, phosphorylation and dephosphorylation of MtlR cysteine 419 by EIIA\textsuperscript{Mtl} plays a pivotal role in induction of the MtlR activity (107). Nevertheless, further experiments are necessary to clarify the interaction between the mannitol-specific PTS transporter components, MtlD and MtlR.

Deletion of the \( mtlR \) gene rendered \( P_{\text{mtlA}} \) and \( P_{\text{mtlR}} \) inactive. This shows that MtlR not only activates the \( mtlAFD \) operon which is reported by Watanabe \textit{et al.} (239), but also acts as an activator for its own promoter. Similarly, \( P_{\text{manR}} \) is also activated by its own product (214). Mutation of the HPr histidine 15 to alanine strongly diminished the \( P_{\text{mtlA}} \) activity to about the same level than that of the deletion of \( mtlR \). This was similar to \( P_{\text{manP}} \) whose activity was very poor in a \( ptsH\)-H15A mutant (214). Indeed, phosphorylation of MtlR by HPr(H15\~P) stimulates the activity of MtlR as shown before for \textit{B. subtilis} LicR (222), LevR (144), and \textit{G. stearothermophilus} MtlR (93). Phosphorylation of the \textit{B. subtilis} MtlR PRDII domain by HPr(H15\~P) was recently shown \textit{in vitro} (107). In addition, mutation of histidine 342 to aspartate which is located at PRDII of \textit{B. subtilis} MtlR was phosphomimetic (see Fig. 3.24). Interestingly, the repression of the \( P_{\text{mtlA}} \) activity by glucose was significantly reduced in the \( mtlR\)-H342D mutant, while the induction of \( P_{\text{mtlA}} \) by mannitol remained unchanged (Fig. 3.24). This phenomenon was also reported by Joyet \textit{et al.} (107). Therefore, dephosphorylation of \textit{B. subtilis} MtlR PRDII acts as catabolite repression (CCR). This is comparable to \textit{G. stearothermophilus} MtlR (93), LevR (144) and LicT in \textit{B. subtilis} (135, 226), Such a CCR was firstly reported for the antiterminator BglG in \textit{E. coli} (76). Finally, electrophoretic mobility shift studies showed that the double mutant MtlR-H342D C419A is active and independent from
phosphorylation by general and specific PTS proteins (Fig. 3.41.B). This confirms that a phosphorylated PRDII and a dephosphorylated EIIB\textsuperscript{Gat}-like domain are essential for an active MtlR. Mutation of the histidine 289 to alanine which is located at the PRDII domain of MtlR significantly reduced the activity of MtlR. In contrast, mutation of the histidine 230 to alanine only slightly decreased the MtlR activity (Fig. 3.24). Similar results are reported by Joyet \textit{et al.} (107). In addition to reduction of \(P_{\text{mtlA}}\) activity, carbon catabolite repression was slightly stronger in PRDI mutants. Apparently, PRDI might be important for the signal transfer from PRDII to the DNA binding domain of MtlR similar to LevR (45). On the other hand, phosphorylation of PRDII by HPr(H15~P) is not independent from PRDI, as reported for \textit{G. stearothermophilus} MtlR (93). Also, it might be possible that mutation of the histidine to alanine affected the MtlR folding or caused structural changes. All in all, more experiments are needed to clarify the role of PRDI in the regulation of MtlR activity.

Glucitol, as a non-specific inducer, activates \(P_{\text{mtlA}}\) and \(P_{\text{mtlR}}\). This effect was first reported by Horwitz and Kaplan when they were studying the mannitol 1-phosphate dehydrogenase activity of crude extracts of \textit{B. subtilis}. They found an increase of mannitol 1-phosphate dehydrogenase activity when \textit{B. subtilis} was cultivated on medium supplemented with glucitol (97). Later, microarray analysis confirmed the induction of \textit{mtlAFD} expression by glucitol (239). Induction of \(P_{\text{mtlA}}\) and \(P_{\text{mtlR}}\) by glucitol was dependent on MtlR and in a \(\Delta\text{mtlR}\) mutant both of these promoters were inactive. On the other hand, deletion of the \textit{gutRBPydjE} had no influence on the induction of \(P_{\text{mtlA}}\) and \(P_{\text{mtlR}}\) by glucitol. Therefore, the activity of \(P_{\text{mtlA}}\) and \(P_{\text{mtlR}}\) caused by glucitol is MtlR-dependent and not GutR-dependent. Similar results were reported by Watanabe \textit{et al.} (239). Besides, the \(\Delta\text{mtlD}\) mutant grew slower than the wild type strain in minimal medium containing glucitol as the major carbon source. Finally, addition of glucitol retarded the growth of the \(\Delta\text{mtlD}\) mutant in LB medium similar to mannitol. In fact, mannitol 1-phosphate dehydrogenase (MtlD) was essential for glucitol assimilation as reported before (239). The induction of the \textit{mtlAFD} genes by glucitol was explained by the non-specific uptake of glucitol by mannitol-specific enzyme II shown by using D-\([\text{14C}]\)glucitol (28). Glucitol is taken up by \textit{B. subtilis} via GutP with no modification and is converted to fructose by glucitol dehydrogenase, GutB (42, 43). When glucitol is taken up by EII\textsubscript{CB}\textsuperscript{Mtl}, glucitol 6-phosphate is generated. The latter product accumulates in the cell and is removed by mannitol 1-phosphate dehydrogenase.
which has a low activity with glucitol 6-phosphate as substrate (97). Taken together, it is assumed that glucitol is taken up by the mannitol-specific EII due to its relaxed specificity in which the transporter can transport more than one sugar. Relaxed specificity of sugar transporters is well-known. For instance, the glucose permease (PtsG) takes up sucrose and salicin, and the β-glucoside permease (BglP) is capable of weak uptake of glucose (189). The uptake and phosphorylation of glucitol leads to activation of MtlR by dephosphorylation of EIIB\textsuperscript{Gat}-like domain. Glucitol 6-phosphate accumulates in the cell and is catabolized slowly by mannitol 1-phosphate dehydrogenase, whereas in the ΔmtlD strain, the accumulation of glucitol 6-phosphate inhibits the cell growth.

4.3. Carbon catabolite repression of \(P_{mtlA}\) and \(P_{mtlR}\)

Addition of glucose represses the \(P_{mtlA}\) and \(P_{mtlR}\) activities in the presence of mannitol. Basically, the presence of glucose increases the level of FBP in the cell causing CcpA-dependent CCR. Therefore, the \(P_{mtlA}\) and \(P_{mtlR}\) activities were investigated in CcpA-dependent CCR-deficient mutants. CcpA forms a DNA binding complex with HPr(S46~P) as its co-effector. Mutation of the regulatory serine 46 of HPr to alanine (\(ptsH\)-S46A mutant) only partially relieved \(P_{mtlA}\) from CCR (Fig. 3.21). Similar to \(mtlAFD\) operon, the \(ptsH\)-S46A mutation partially or completely relieves many other catabolic operons from CCR, such as \(xylAB\) (37), \(bglPH\) (116), \(levDEFG\) (146), \(gntRKPZ\) (181), \(manPA\) (214). Besides HPr(S46~P), Crh(S46~P) can also form a complex with CcpA inhibiting the catabolic operons. Deletion of Crh abolishes the residual CCR for many genes, such as \(acsA\) (262). Accordingly, \(P_{mtlA}\) activity was measured in a Δ\textit{crh} mutant as well as in a \(ptsH\)-S46A Δ\textit{crh} double mutant. Deletion of \textit{crh} alone did not affect the CCR of \(P_{mtlA}\), while CCR of \(P_{mtlA}\) in the \(ptsH\)-S46A Δ\textit{crh} double mutant was similar to the \(ptsH\)-S46A mutant in which \(P_{mtlA}\) activity was reduced (Fig. 3.21). In fact, Crh plays a minor role as the CcpA effector for CCR (202). Recently, it is found out that unphosphorylated Crh mainly inhibits methylglyoxal synthase (MgsA) activity. In this way, the cell prevents the accumulation of phosphosugars under carbon overflow condition (122). This could explain the lower \(P_{mtlA}\) activity in both the Δ\textit{crh} \(ptsH\)-S46A and Δ\textit{crh} mutants (Fig. 3.21). In the absence of Crh, MgsA constantly converts dihydroxyacetone phosphate to methylglyoxal. Methylglyoxal is afterwards
excreted into the extracellular milieu or further converted to pyruvate. Altogether, the PEP production is reduced due to the loss of DHAP causing a lower amount of HPr(H15~P). In addition, methylglyoxal seems to be toxic for the cells. Coeffectors Crh and HPr are both phosphorylated by HPrK/P as a result of high FBP concentration in the cell. Transcriptome analyses of B. subtilis indicated that deletion of hprK (encoding HPrK/P) resulted in a loss of CcpA-dependent CCR (139). Deletion of hprK, however, did not significantly affect the CCR of P<sub>mtlA</sub>. Besides, the ΔhprK mutant grew significantly slower than the wild type strain. Finally, ccpA, encoding the master regulator of CCR, was deleted. Unexpectedly, the P<sub>mtlA</sub> activity in a ΔccpA was strongly repressed by glucose, although the P<sub>mtlA</sub> activity in the ΔccpA mutant was significantly lower than in wild type strain. The observed high CCR of P<sub>mtlA</sub> in the ΔccpA mutant could be due to an alteration of the cell physiology. In fact, CcpA is a pleiotropic regulator controlling important metabolic pathways, such as glycolysis (112, 141, 223), ammonium assimilation (34, 56, 234), excretion of excess carbon source, and fermentation (210). In addition, P<sub>mtlA</sub> could be also indirectly subjected to CCR via mtlR expression. Production of MtlR is prerequisite for induction of P<sub>mtlR</sub>. Any depletion in the MtlR amount in the cytoplasm is supposed to change the transcription of P<sub>mtlA</sub> drastically. Accordingly, it is assumed that CCR could mainly alter the transcription of P<sub>mtlA</sub>, thereby controls the P<sub>mtlA</sub> activity. Indeed, P<sub>mtlR</sub> has relieved from CCR in the ΔccpA mutant, albeit partially. Reduction of CCR in P<sub>mtlR</sub> has also occurred in the ptsH-S46A Δcrh double mutant, although the basal activity was doubled in the latter mutant. In summary, any disruption of trans elements of the CcpA-dependent CCR only partially relieved P<sub>mtlR</sub> and P<sub>mtlA</sub> activities from CCR. On the other hand, analyses of P<sub>mtlA</sub> and P<sub>mtlR</sub> sequences revealed putative cre sites resembling cre consensus sequence (WTGAARCGNWWAC). These putative cre sites of P<sub>mtlA</sub> and P<sub>mtlR</sub> overlapped the -10 boxes. By these means, binding of the CcpA-HPr(S46~P) complex to the cre site prevents the binding of RNAP by a steric hindrance mechanism. Interestingly, the cre sites of P<sub>mtlA</sub> and P<sub>mtlR</sub> lack the conserved cytosine at the end of cre sequence. It is likely that the left-side TG bases in WTTGAARCGNWWCA sequence are required for pairing with the right-side CA bases resulting in the proper binding of CcpA-HPr(S46~P) complex (61). This cytosine plays an essential role in the operation of cre sites of amyE, gntR, and hutP (62, 240, 248). In order to repair the cre sites of P<sub>mtlA</sub> and P<sub>mtlR</sub>, the conserved right-side CA bases were introduced in P<sub>mtlA</sub>
and $P_{mltR}$ putative cre sites (Fig. 3.44). Alteration of the cre sites rendered $P_{mltA}$ and $P_{mltR}$ inactive. Perhaps, mutation in the second position (underlined) of the -10 box (TATAAT) in $P_{mltA}$ and $P_{mltR}$ and addition of a cytosine to this AT-rich hexamer deactivated the promoters. On the contrary, mutation of the conserved left-side TG for further disruption of the putative cre site of $P_{mltA}$ did not alter the CCR of $P_{mltA}$ (Fig. 3.43 and Fig. 3.45). Disruption of $P_{mltR}$ cre site, however, partially reduced the $P_{mltR}$ CCR. First interpretation may point out that the $P_{mltR}$ cre site was functional, whereas the $P_{mltA}$ cre site was inefficient. However, in all of the undertaken experiments, the CCR of $P_{mltR}$ affects the $P_{mltA}$ CCR. To remove the influence of $P_{mltR}$ cre on $P_{mltA}$ CCR, the cre sites of $P_{mltA}$ and $P_{mltR}$ were fused to a constitutive promoter whose activation is independent from mannitol induction. In this way, it was shown that the cre sites of $P_{mltA}$ and $P_{mltR}$ are partially able to block the transcription initiation of $P_{groE}$. Besides, the cre site of $P_{mltR}$ was more efficient than $P_{mltA}$. Fujita analysed 50 reported cre sites of B. subtilis. This analysis revealed two groups of cre sites including: WTGNAANCGNWWNCA (group A) and WTGAAARCGYTTWNN (group B) (61). In group A, pairing the TG and CA (underlined) is essential for an operational cre site. In the group B, this pairing is compensated by A and T pairs (underlined), as shown for iolA cre site (153). Altogether, it seems that the sequences in $P_{mltA}$ and $P_{mltR}$ belong to the group B cre sites where palindromic A’s and T’s are necessary for binding the CcpA-HPr(S46~P) complex. In this way, $P_{mltA}$ has a weak cre site, as experimentally shown, due to the presence of two mismatches (underlined) to the group B consensus sequence (CTGTAAGCGTTTAAA). Unlike the $P_{mltA}$ cre site, the cre site of $P_{mltR}$ contains no mismatches compared to the group B cre consensus sequence. These cre sites are likely weaker than the group A cre sites as indicated by comparison of cre sites of acsA, $P_{mltA}$ and $P_{mltR}$. Consequently, the CcpA-dependent CCR is mediated by two weak cre sites located at $P_{mltA}$ and $P_{mltR}$ at the transcription initiation level.

In addition to CcpA-dependent CCR, CcpA-independent CCR mediated by HPr (a.k.a. induction prevention) was also studied. Uptake of glucose reduces the concentration of HPr(H15~P), thereby reduces the activity of the regulators by induction prevention (61, 75). To prevent the uptake of glucose, the glucose-specific PTS transporter encoded by ptsG was deleted. Here, it is shown that $P_{mltA}$ and $P_{mltR}$ in a ΔptsG mutant were fully active in the simultaneous presence of mannitol and glucose. In other words, glucose repression was completely abolished.
in the ΔptsG mutant. This phenomenon was previously shown for the bglPH operon by the mutation of EIICBA_Glc residues (6) and in gntRKPZ operon by insertional mutagenesis of ptsG (171). Apart from EIICBA_Glc, there are two other glucose transporters in B. subtilis, namely GlcP and GlcU. However, both of these transporters are not expressed during the exponential phase (58, 159, 171). Recently, it was shown that the uptake of D-[14C]glucose did not occur only in a ΔptsG mutant (100). Thus, in addition to HPr-mediated CCR, the CcpA-dependent CCR is also not functional in a ΔptsG mutant due to low level of FBP pool in the cell. Previous experiments (see above) showed that disruption of CcpA-dependent CCR components causes only a partial reduction in P_mtlA or P_mtlR CCR. Thus, it seems that depletion of HPr(H15~P) and induction prevention mainly causes CCR of the mtlAFD operon. This is in line with our previous observations with the MtlR-H342D mutant, where MtlR was highly active in the presence of glucose (strain KM213; Fig. 3.24). Likewise, the activity of P_mtlA was repressed in the presence of fructose. In contrast, sucrose and mannitol had no significant influence on the P_mtlA activity. Glucose, fructose, mannitol, and sucrose are the preferred carbon sources of B. subtilis. All of these sugars are taken up by PTS and exert strong CCR in other catabolic operons, such as in xynPB operon encoding the β-xyloside utilization system (202). Taken together, it is probable that HPr-mediated CCR of P_mtlA and P_mtlR is caused by the dephosphorylation of HPr(H15~P) by glucose- and fructose-specific transporters. Apparently, there is also a hierarchy between the preferred carbon sources in B. subtilis. Perhaps, HPr(H15~P) has a higher affinity towards glucose and fructose PTS permeases than mannitol-, mannose- and sucrose-specific EII. Besides, it might be possible that the PRDII domain of MtlR is directly dephosphorylated by glucose and fructose PTS permeases. Both of these assumptions need more experimental evidence. In conclusion, the carbon catabolite repression acts at two levels in mannitol PTS: the transcriptional level caused by CcpA-dependent CCR and posttranslational level caused by HPr (or likely PtsG) modulating the MtlR activity via PRDII domain phosphorylation.

4.4. Translation initiation and construction of an expression system

A mannitol-inducible expression system in B. subtilis was constructed based on P_mtlA due to its stronger activity than P_mtlR (discussed in section 4.1). In order to enhance the P_mtlA activity,
the transcriptional and translational initiation regions were manipulated. At first, the $P_{mtlA}$-10 box was replaced with the consensus -10 hexamer (TATAAT) of the $\sigma^A$-type promoters. This replacement only increased the basal activity, but not the $P_{mtlA}$ maximal activity. Presumably, the similarity of $P_{mtlA}$ core elements to the consensus $\sigma^A$-type promoter core elements reduces $P_{mtlA}$ dependency to an activator. Another key factor for controlling the protein synthesis is the abundance of mRNA. Accordingly, instead of changing the $P_{mtlA}$ core elements, the translation initiation was studied by shortening of the 5’ leader sequence of mtlA mRNA in the $P_{mtlA}$-lacZ cassette on pKAM1 (Fig. 3.48.A). Also, the 5’UTR of mtlR mRNA on pKAM3 was shortened (Fig. 3.8.A). Basically, cellular mRNA concentration depends upon the rates of its synthesis and degradation. The mechanism of mRNA degradation and the half-life of mRNA are not clear for the mtlA and mtlR mRNAs. Nevertheless, having an optimal ribosomal binding site at the 5’-end of an mRNA, and in a consequence a high translation rate, appears to protect the mRNA against 5’ to 3’ exonuclease activity, as shown in gsiB mRNA (108). In addition to an optimized ribosomal binding site, thermo-responsive RNA structures also modulate the translation initiation (109). Characterization of the $P_{mtlA}$ and $P_{mtlR}$ transcription start sites showed long 5’ leader sequences in mtlA mRNA and mtlR mRNA. The length of 5’-UTR of mtlA mRNA was 72 bp, whereas 5’-UTR of mtlR mRNA is 77 bp long. After construction of pKAM1 harboring the $P_{mtlA}$-lacZ cassette, two ribosomal binding sites were placed upstream of the lacZ (Fig. 3.2.A). This first one was originated from mtlA (shown by RBS W) and the second one from bacteriophage T7 (shown by RBS V). Interestingly, shortening of the 5’ leader sequence of mtlA mRNA in pKAM12 and pKAM50 dramatically increased the expression of lacZ compared with pKAM1. This increase of the $P_{mtlA}$ activity could be presumably because of the deletion of one of the ribosomal binding sites, namely the mtlA RBS. On the other hand, analysis of the deleted region in 5’UTR of the mtlA mRNA revealed an incomplete inverted repeat adjacent to the ribosomal binding site (Fig. 4.2). This incomplete inverted repeat could cause a secondary structure near the ribosomal binding site, thereby creating a spatial hindrance for binding the ribosome. Likewise, it could form a loop which inhibits the mRNA decay by the RNase J1 as reported for gapA mRNA (131). Altogether, partial deletion or complete deletion of this inverted repeat increases the activity of $P_{mtlA}$.
Fig. 4. 2. The 5’ leader sequence of *mtlA* mRNA on pKAM1. Transcription start site of *P*<sub>mtlA</sub> is shown by +1. The RBS demonstrates the ribosomal binding site of *mtlA*. The 5’ leader sequence of *mtlA* mRNA fused to *P*<sub>mtlA</sub> core elements in pKAM1, pKAM12 and pKAM50 are represented by solid and dashed lines. The incomplete inverted repeat is shown by arrows and highlighted in gray.

Unlike 5’ UTR of *mtlA* mRNA, shortening of 5’UTR of the *mtlR* mRNA gradually decreased the expression of lacZ. The *P*<sub>mtlR</sub>-lacZ fusion on pKAM3 contained two simultaneous ribosomal binding sites (Fig. 3.6.A). However, deletion of the second ribosomal binding site, RBS of *mtlR* decreased the activity of *P*<sub>mtlR</sub>. By viewing the sequence of 5’UTR of *mtlR* mRNA, two repeats, *i.e.* ACCTC and CTCCT, were found complementary to the ribosomal binding site (Fig. 4.3).

Fig. 4. 3. The 5’ mRNA leader sequence of *mtlR* on pKAM3. Transcription start site of *P*<sub>mtlR</sub> is shown by +1. The RBS demonstrates the ribosomal binding site of *mtlR*. The 5’ mRNA leader sequence of *mtlR* fused to *P*<sub>mtlR</sub> core elements in pKAM3, pKAM18, pKAM86, and pKAM87 are represented by solid and dashed lines. The incomplete inverted repeat is shown by arrows and highlighted in gray.

It is likely that these repeats form stable secondary structures with ribosomal binding sites. Therefore, the presence of the second RBS from *mtlR* may prevent the formation of a secondary structure between the vector RBS and the found repeats. It must be noted that in the pKAM86 and pKAM87 constructs two longer palindromic sequences were formed overlapping the ribosomal binding site (data not shown). Further experiments are necessary to analyze the stability of the *mtlA* and *mtlR* mRNAs.
Ultimately, a mannitol expression vector system was constructed by changing the parental vector (pBS72 which is a low copy vector) to a pUB110 derivative with high copy number. Similar to Wenzel et al. (242), the translational initiation region of gsiB which has a stable mRNA due to an optimized RBS was used (108). Comparison of the mannitol-inducible expression system with the already described mannose-inducible system (242) showed that the expression of eGFP was half of the mannose-induced system. One of the major problems by increasing the copy number of a gene is the regulator copy number and titration of the regulator and the binding site. In comparison with $P_{\text{mtlR}}$, the activity of $P_{\text{manR}}$ is about 10-fold higher (214). Therefore, a single copy of $P_{\text{manR}}$-$\text{manR}$ on the chromosome supports the activity of $P_{\text{manP}}$ on a high copy number vector. Increasing the copy number of $\text{mtlR}$ by insertion of $P_{\text{mtlR}}$-$\text{mtlR}$ on the expression vector increased the $P_{\text{mtlA}}$ activity to the level of mannose-inducible system. However, the basal activity was increased. In fact, a delicate balance between the expression of MtlR and the copy number of $P_{\text{mtlA}}$ is necessary.
5. Conclusion and perspectives

The aim of this study was to analyze the regulation of the mannitol utilization system in *B. subtilis*. Phosphorylation and dephosphorylation of the MtlR domains by specific and general proteins of the PTS plays the pivotal role in the regulation of mannitol utilization system. The observed carbon catabolite repression for the $P_{mtlA}$ and $P_{mtlR}$ activities is also mainly functional at post translational level in the mannitol utilization system by affecting the phosphorylation status of MtlR. The CcpA-dependent pathway affected the transcription of the *mtlAFD* operon as well as the *mtlR* gene to a less content. Finally, an expression vector system has been constructed by using the $P_{mtlA}$ sequence, which is highly inducible by mannitol. However, further characterization and optimization of this system must be done. Some further perspectives of this work are listed below:

- Confirmation of the MtlR and αCTD binding sites located on $P_{mtlA}$ and $P_{mtlR}$ in vitro.
- Analyze the structures of *mtlAFD* and *mtlR* mRNAs and its mRNA stability.
- Characterization of the possible antisense RNAs resided within *mtlAFD* operon and their influence on the *mtlAFD* operon and *mtlR* regulation.
- Characterization of the role of PRDI in the regulation of MtlR as a PRD-containing activator and studying the probable interaction of the MtlR domains with each other and probably with PtsG.
- Improvement of the *mtl* expression system by increasing the stability of the pUB110 derivative plasmid pKAM114.
