Abstract. A study of low energetic resonant Raman scattering of (BEDT-TTF)$_2$I$_3$ superconductors was performed. The vanishing of phonon bands accompanied by a decrease of the electronic background was observed below $T_c$. We propose a theoretical explanation for this novel effect in terms of the Balseiro-Falicov model of phonon-superconducting amplitude mode interaction.

Introduction

The organic superconductors with the highest transition temperatures are all radical salts of the donor bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF). Of special interest are the several structural different phases of the radical salt (BEDT-TTF)$_2$I$_3$ [1–11]. These (BEDT-TTF)$_2$I$_3$ systems have undergone intensive experimental and theoretical scrutiny, most of which have been devoted to the understanding of the nature of the superconducting mechanism in these compounds. The Raman spectroscopy is a useful tool for this purpose because it is based on the electron-phonon interaction and therefore is able to probe sensitively both the phonon and the electronic subsystems as well as their coupling. Abrikosov and Falicovskii [12] showed that the presence of an energy gap in the electronic energy spectrum of superconductors leads to the absence of absorption (at $T = 0$) of radiation with frequencies less than the threshold frequency, equal to the energy gap $2\Delta$.

The method to determine the superconducting gap magnitude of the high-$T_c$ superconductors (HTSC) from the Raman scattering spectra is based on this idea. Raman scattering spectra of the HTSC above $T_c$ consist of an almost constant background attributed to electronic excitations and superimposed structures due to scattering from phonons. In the superconducting state the electronic scattering strength decreases for low frequencies, overshoots the normal conducting one in the middle frequency region, and asymptotically approaches unity for high energy transfers [13–16].

Beside this observation a softening of some of the Raman-active modes at $T_c$ in the crystals of RBa$_2$Cu$_3$O$_{7-\delta}$ (R is a rare earth) was noticed [17–19]. This fact was interpreted by the existence of the energy gap above the mode frequency. Sometimes a reduced background scattering below $T_c$ at a frequency below the softened mode was observed as well [19]. An anomalous intensity change of Raman-active phonons in YBa$_2$Cu$_3$O$_{7-\delta}$ below the superconducting transition temperature was observed by Friedl et al. [20]. It was explained by a superconductivity-induced resonant Raman process originating from the resonance of the phonons with the superconducting gap. From the above remarks one can see that Raman scattering from superconducting gap excitations in HTSC can give information of the pairing mechanism as well as of the nature and the value of the gap.

(BEDT-TTF)$_2$I$_3$ is an unique system for Raman scattering investigations. Several phases with rather high $T_c$ exist inside this family which are suitable for Raman measurements. First of all, it is the $\alpha$-phase with a $T_c$ = 8–8.5 K which can be produced from the $\alpha$-phase by tempering the crystals at temperatures higher than 75 °C [10, 11], and the $\beta_{\text{Ir}}$-phase ($T_c$ = 8 K) which appears on the surface of $\beta$-phase crystals due to irradiation with a laser [9].

Perhaps the most important feature for Raman investigations of this system is the existence of several low energetic optical phonon bands assigned to $I_3$ anion stretching modes as well as of librations of the BEDT-TTF molecule, which are rather intensive due to resonance conditions of their excitation [9, 21]. The energy of these bands is close to the expected energy of the gap and therefore those bands might be sensitive to the formation of a gap.
The aim of our study was to measure the low-energy resonant Raman scattering data in single crystals of \((\text{BEDT-TTF})_2 I_3\) below and above \(T_c\) in order to obtain information whether a formation of a gap occurs.

**Experimental**

Raman measurements on single crystals were made in a 90° scattering configuration using several lines of an argon-ion laser (Coherent Innova 90). Since the Raman scattering on the \(I_x\)-anions in the organic superconductors \((\text{BEDT-TTF})_2 I_3\) has a resonant character [9], with a maximum for \(\lambda = 488\) nm, the majority of our studies have been performed for an excitation with laser light of this wave-length. The maximum intensity of the symmetric stretching mode of \(I_3^+\), at about 120 cm\(^{-1}\) served as an indication of a proper laser beam adjustment and polarization. The intensity of the band at 120 cm\(^{-1}\) was maintained at a constant level and was controlled during the temperature measurements. The laser beam was filtered with a monochromator and an additional interference filter in order to suppress plasma lines. A SPEX 1404 double monochromator with a spectral resolution of 0.14 cm\(^{-1}\) was used to disperse the scattered radiation. The power of the laser beam was maintained at about 25 mW and not completely focused in order to prevent sample damages. For some crystals the spectra were studied for lower or higher laser powers. The focusing of the light was also adapted to the peculiarities of the sample surface. Sometimes the best spectra of samples with distinctly nonhomogeneous surfaces were measured with strongly focused light. The spectra were investigated with different slit widths, but no larger slits than 300 \(\mu\)m were used, which guarantees a resolution better than 1 cm\(^{-1}\). The Raman shifts between 6 cm\(^{-1}\) and about 150 cm\(^{-1}\) have been investigated for temperatures from about 50 K down to 1.5 K.

\(\alpha\)- and \(\beta\)-(BEDT-TTF)\(_2\) \(I_3\) crystals were grown from a THF solution by electrochemical methods as described earlier [1]. The single crystals with highly reflecting surfaces were selected for Raman measurements as well as for preparing the \(\alpha\)-(BEDT-TTF)\(_2\) \(I_3\) phase. For this purpose \(\alpha\)-(BEDT-TTF)\(_2\) \(I_3\) crystals were annealed in air for 1–6 d at temperatures between 75 and 95 °C. We observed that \(\alpha\)-phase crystals tempered at 75 °C during 1–3 d kept their shapes much better than those tempered at higher temperatures. However, an attentive analysis of the Raman spectra of those crystals in the region of the stretching and bending modes of \(I_3^+\) indicated an incomplete transformation into the \(\alpha\)-phase. On the other hand tempering at 75 °C during about 6 d caused considerable degradation of the crystal surface. A microscopic examination of the surface revealed numerous and large areas of completely degraded salt (orange spots of neutral donor BEDT-TTF). Besides, numerous cracks and breaks were observed. The surface of so tempered \(\alpha\)-(BEDT-TTF)\(_2\) \(I_3\) samples was nonhomogeneous, mat and strongly dispersive. Our attempts to remove the degraded surface layer by a THF-bath did not lead to improve the crystal surface. Crystals of \(\alpha\)-(BEDT-TTF)\(_2\) \(I_3\) tempered at 95 °C for times shorter or equal to one day were most suitable for Raman measurements. Their surface, in spite of corrugation, was reflective and suitable for the studies.

The penetration depth of the laser light estimated from absorption coefficient was calculated from the spectra of single crystals of \((\text{BEDT-TTF})_2 I_3\) [22] and is about 1000 nm. This low value explains the sensitivity of the Raman spectra to the surface quality of the samples.

Our remarks on the quality of the \(\alpha\)-(BEDT-TTF)\(_2\) \(I_3\) surface layer were confirmed by electrical conductivity measurements performed for samples tempered at 75 °C as well as 95 °C. Both tempering procedures lead to a transformation of the \(\alpha\)-phase into the \(\alpha\)-phase in the bulk; it is seen as a transition to the superconducting state at about 8 K. A small remainder of the \(M-I\) phase transition at 135 K in the \(\alpha\)-phase can still be seen in both cases. Nevertheless, some contact resistance instabilities and nonregularities were observed above the \(M-I\) phase transition temperature for the sample tempered at 75 °C during a few days. In this region the resistivity of the contacts is comparable to the resistivity of the sample. Some random changes at the contacts between the surface layer and the bulk of the crystal are responsible for this instabilities. Such an effect is not observable for the samples tempered shortly at 95 °C. This means that the surface of the crystals tempered at 95 °C is also transformed into the \(\alpha\)-phase and therefore those crystals are relatively homogeneous and non-decomposed at the surface.

**Results**

The Raman spectra of the \(\alpha\)- and \(\alpha\)-(BEDT-TTF)\(_2\) \(I_3\) phases for an excitation of \(\lambda = 488.0\) nm at \(T = 1.5\) K are shown in Fig. 1. These spectra are similar to those reported by Swietlik et al. [9, 11]. However, the spectrum of \(\alpha\)-(BEDT-TTF)\(_2\) \(I_3\) (Fig. 1c) is a little bit different. In the good crystals of \(\alpha\)-phase we observed only weak lines in these cases are shifted more than 15 cm\(^{-1}\) from the plasma lines. Some random changes at the contacts between the surface layer and the bulk of the crystal are responsible for this instabilities. Such an effect is not observable for the samples tempered shortly at 95 °C. This means that the surface of the crystals tempered at 95 °C is also transformed into the \(\alpha\)-phase and therefore those crystals are relatively homogeneous and non-decomposed at the surface.

In addition a plasma line would be much narrower. An clear band was also observed at \(T > T_c\) (Fig. 2).

- a $(BEDT-TTF)_2 I_3$
- b $\alpha/\alpha_t (BEDT-TTF)_2 I_3$
- c $\alpha_t (BEDT-TTF)_2 I_3$

$\alpha_t (BEDT-TTF)_2 I_3$, $\alpha/\alpha_t (BEDT-TTF)_2 I_3$ and $\alpha_t (BEDT-TTF)_2 I_3$ observed below $150 \text{ cm}^{-1}$ at $T=1.5$ K, excited by light of a wavelength of $\lambda=488.0$ nm.

The linewidth $\Delta \omega$ of the symmetric stretching mode of $I_3^-$ for $\alpha_t (BEDT-TTF)_2 I_3$, at $120.5 \text{ cm}^{-1}$ is $4.5 \text{ cm}^{-1}$ and is a little bit larger than the strongest band of the analogue triplet band observed for the $\alpha$-phase. The spectrum for the non-totally transformed $\alpha$-phase crystals (Fig. 1b) shows the main features of both $\alpha$- and $\alpha_t$-phases. The band at $120 \text{ cm}^{-1}$ in this case is considerably broadened ($\Delta \omega = 7 \text{ cm}^{-1}$) in comparison to the line of $120.5 \text{ cm}^{-1}$ for $\alpha_t (BEDT-TTF)_2 I_3$. The observed resonance Raman frequencies for $\alpha$, $\alpha_t$ and non-totally transformed $\alpha_t (BEDT-TTF)_2 I_3$ (in the following we will call those crystals $\alpha/\alpha_t (BEDT-TTF)_2 I_3$), are collected in Table 1. The spectra of the $\beta$- and $\beta_{HT}$-phases are similar to the spectra shown in [9] and [11].

Intensity: vs – very strong, s – strong, m – medium, w – weak and vw – very weak
Figure 2 shows the low energetic parts (below 50 cm$^{-1}$) of the resonant Raman spectra of the $\alpha/\alpha'$-phases of (BEDT-TTF)$_2$I$_3$ at 1.5 K ($T<T_c=8$ K) and at $T>T_c$. A relatively strong increase in intensity of both bands at 31.5 cm$^{-1}$ and 38.5 cm$^{-1}$ as well as an increase of the background scattering is observed in the normal (non-superconducting) phase of $\alpha_a$(BEDT-TTF)$_2$I$_3$. Beside this observation a considerable softening of the low-frequency band is seen (Fig. 2a). Above the phase transition in crystals of $\alpha/\alpha_a$(BEDT-TTF)$_2$I$_3$ a distinct broadening and shifting of the band at about 30 cm$^{-1}$ is observed; some increase of the background scattering is seen as well (Fig. 2b). It is necessary to add that a further increase of the temperature up to about 60 K i.e. $T=7.5T_c$ does not change the spectra perceptibly. The spectra of control samples of $\alpha_a$(BEDT-TTF)$_2$I$_3$ (which do not become superconducting) at $T=1.5$ K and 10 K $< T < 60$ K did not undergo any changes.

Our Raman investigations on crystals of $\beta$(BEDT-TTF)$_2$I$_3$ confirmed a transformation of this material into the $\beta_p$-phase under illumination with laser light. The transformation induced by the laser light appears as a typical evolution of the split mode $v_1$ of the I$_3$-anions in $\beta$(BEDT-TTF)$_2$I$_3$, similar as described in [9]. The low-energetic part of the resonance Raman spectra of $\beta_p$(BEDT-TTF)$_2$I$_3$ (Fig. 3) contains two very weak and broad bands at about 22-24 cm$^{-1}$ and 30-32 cm$^{-1}$. The intensity of the bands was comparable to the noise level for totally transformed $\beta_a$-samples, at 1.5 K. Above the phase transition temperature ($T_c=8$ K) an appearance of the bands at 22.5 cm$^{-1}$ and 30.5 cm$^{-1}$ was observed. It should be emphasized that the above mentioned bands as well as the split band at 109 cm$^{-1}$ and 126 cm$^{-1}$ [9] show only a small dependence on the laser polarization in contrast to the intensities of the bands for the $\alpha$- and $\alpha/\alpha_a$-phases which strongly depend on the polarization of the laser light.

The comparison of the low-energy resonant Raman scattering spectra of $\alpha_a$(BEDT-TTF)$_2$I$_3$ (Fig. 2a) for temperatures below (spectrum $A$) and above (spectrum $B$) the phase transition temperature $T_c$ reveals relatively large changes. The spectra of $\beta_p$(BEDT-TTF)$_2$I$_3$ (Fig. 3) show the same tendency as those of $\alpha_a$(BEDT-TTF)$_2$I$_3$, but the phonon modes are shifted to somewhat smaller energies. The situation is more complicated for the $\alpha/\alpha_a$(BEDT-TTF)$_2$I$_3$ sample; it is a mixture on the surface of the sample of $\alpha_a$-phase and non-transformed $\alpha$-phase. Thus the bands at about 30 cm$^{-1}$ and 38 cm$^{-1}$ (Fig. 2b) observed at $T=1.5$ K should be assigned to librations of the BEDT-TTF molecules of $\alpha$(BEDT-TTF)$_2$I$_3$. A small shift of the mode frequencies (about 1 cm$^{-1}$) in comparison to single crystals of $\alpha$(BEDT-TTF)$_2$I$_3$ is caused probably by defects and stresses induced by the annealing procedure of the crystals. At $T>T_c$ a distinct broadening and shifting of the phonon band at 30 cm$^{-1}$ is observed (curve $B$ in Fig. 2b). Assuming that the background at $T>T_c$ is approximated by the spectrum at $T=1.5$ K we get a spectrum of the $\alpha/\alpha_a$-crystal transformed into the superconducting state as a difference between spectra $B$ and $A$ (Fig. 2b, line $C$).

Figure 4 shows the experimental electronic part of the Raman scattering of $\alpha_a$(BEDT-TTF)$_2$I$_3$ at $T=1.5$ K normalized to scattering at $T>T_c$. It should be noticed that this scattering decreases below 33 cm$^{-1}$ but starts to increase again strongly below 25 cm$^{-1}$.

**Discussion**

In our experiments we have observed a softening and weakening of the low frequency optical phonons at about 30 cm$^{-1}$ in the superconducting state of $\alpha_a$ and $\beta_p$(BEDT-TTF)$_2$I$_3$.

A similar weakening of a low frequency "phonon" mode in the superconducting state was observed by Sooryakumar and Klein in NbSe$_2$ [23], using Raman spectroscopy. The "phonon" is in fact a CDW mode at a frequency of about 30 cm$^{-1}$. The weakening of the Raman line of this mode, as the temperature is lowered below $T_c$, is associated with the building-up of another mode at about 17 cm$^{-1}$, i.e. the superconducting gap energy $2\Delta$. This mode is an amplitude-mode of the gap parameter, i.e. is associated with a spatial modulation of the amplitude of the superconducting gap: $\Delta(R) = A_0 + \delta A \cos(q \cdot R)$, where $q$ is the wave vector of the...
amplitude mode. This mode is a Higgs mode, with a finite frequency as \( q \rightarrow 0 \), given by \( 2\Delta \) in an “ideal” superconductor [24]. The sum of the intensities of the Raman lines due to the amplitude mode and the “phonon”, was found to be approximately constant up to 9 K (\( T_c \approx 7 \) K). Thus, the intensity of the amplitude mode is taken away from the “phonon”.

This phenomenon was interpreted theoretically by Balseiro and Falicov [25]. They considered the self-energy \( \Pi(q, \omega) \) of a phonon, coupled with the amplitude mode in the superconducting state. This coupling should, in principle, shift the frequencies of both the phonon and the amplitude mode, pushing them apart, as well as reduce the Raman amplitude of the phonon mode. For the case of NbSe\(_2\), they estimate the electron-“phonon” coupling constant of \( \lambda = 2g^2 \rho_0/h \omega_0 = 0.24 \) and because of this small value, the reduction of the amplitude and frequency shifts are only about 10%.

The amplitude mode exists only for small values of \( q_i \), \( q < \xi^{-1} \), where \( \xi \) is the coherence length. Thus, only phonons with small \( q \) should be affected by the mixing with these modes. Note, that when the phonon and the superconducting amplitude mode mix, each one is partly “phonon” and partly a “superconducting gap” mode.

Littlewood and Varma [26] showed that the coupling between the “phonon” and amplitude mode depends not only on the electron phonon coupling constant \( \lambda \), but also on another coupling constant \( \alpha \) related to the depression of \( T_c \) by the CDW. Estimating \( \alpha \), they accounted for the decrease in intensity of the “phonon” Raman line by 10%, and the intensity and position of the amplitude mode, as observed experimentally.

Zwicknagl and Zeyher [27] showed that in principle, the mode at 17 cm\(^{-1}\) may be a CDW mode (rather than a superconducting amplitude mode), the role of superconductivity being just to reduce dissipations and thus prevent this mode from being excessively broadened.

In \( \alpha_r \) and \( \beta-(BEDT-TTF)\_2 I_3 \) we have a situation in which the low frequency phonon mode is a real optical phonon (rather than a CDW mode) of frequency \( \approx 30 \) cm\(^{-1}\). Therefore, its coupling with the electrons is expected to be much stronger. The observed phonons at around 30 cm\(^{-1}\) and 39 cm\(^{-1}\) are probably librations of the BEDT-TTF-molecules, which are optical modes, i.e. \( \omega(q) \) is finite as \( q \rightarrow 0 \). Such modes have a strong quadratic interaction with the electrons in linear chain compounds [28], but interact linearly with the electrons in the two-dimensional BEDT-TTF salts [29], and the interaction is expected to be very strong as well. Tunneling measurements indicate that essentially all the electron phonon coupling is with these phonons [30]; therefore, in order to account for the observed \( T_c \approx 8 \) K, \( \lambda \) must be close to 2. Therefore, both the shift of the phonons and the reduction of their amplitudes, must be much larger than in NbSe\(_2\), and the phonon lines should practically disappear in the superconducting state, as found in our experiments.

However, here we are faced with the dilemma, where does the amplitude of the phonon Raman line go to? In the Balseiro and Falicov (BF) theory [25], the amplitude goes to the amplitude mode at \( 2\Delta \). For \( T_c = 8 \) K and assuming a BCS type superconductor \( 2\Delta_{BCS} \approx 2.5 \) meV = 20 cm\(^{-1}\). Our experimental data do not show any change in the Raman scattering there, or in any other part of the investigated region.

More recent tunneling measurements on \( \alpha_r-(BEDT-TTF)\_2 I_3 \) [30] show large, very sharp peaks in two regions, namely 0.7 meV ± 6 cm\(^{-1}(2\delta_{II})\), and 10 meV ± 80 cm\(^{-1}(2\delta_{III})\) (and in addition, a second harmonic at 20 meV).

The “conventional” interpretation would associate \( \delta_{II} \approx 40 \) cm\(^{-1}\) with the superconducting gap which thus would be about four times larger than the expected BCS gap. However, we prefer to associate \( \delta_{II} \) with the phonon frequency \( \omega_{ph} \), or with \( \omega_{ph} + \Delta_{BCS} \), i.e. we consider this structure as a “giant” McMillan-Rowell peak [31, 32]. It is observed at \( 2(\omega_{ph} + \Delta_{BCS}) \) because there are 2 superconducting-normal (s-n) junctions in series in this experiment [30].

We suggested that the structure near 6 cm\(^{-1}\) is the superconducting gap (mixed with the phonon), i.e. the smallest excitation energy in the system [30]. Because of its low energy, it is denoted “zero bias anomaly” and we suggested that it is analogous to the structure observed in YBaCuO at 4 meV [33]. This suggestion is supported by the following observations on another BEDT-TTF radical salt, namely \( \kappa-(BEDT-TTF)_2 Cu(NCS)_2 \), where the situation seems to be very similar to \( \alpha_r \) and \( \beta-(BEDT-TTF)_2 I_3 \).

\( a) \) Infrared absorption measurements by Kornelson et al. [34] on this salt (\( T_c = 10.4 \) K) show that there is no change around 20-25 cm\(^{-1}\) in the superconducting state, i.e. there is (apparently) no superconducting gap there. In contrast, surface impedance measurements by Holzer et al. [35] around 3 cm\(^{-1}\) show a large change in the surface impedance in the superconducting state, indicating that the gap must exceed this energy. A superconducting gap of about 6-8 cm\(^{-1}\) reconciles these apparently conflicting observations.

\( b) \) Measurements of the temperature dependence of the London penetration depth show a power-law dependence, rather than the expected BCS exp(-2\( \Delta/k_BT \)) dependence [36] (it should be mentioned that in contrast to the power-law dependence found in [36] the group of Grünner finds a BCS-like behaviour in the same compound [35]). If the lowest excitation energy is indeed 3-4 times smaller than the BCS-gap, such a power-law dependence in the investigated temperature range is to be expected.

If there is a strong coupling between an optical phonon at 30-39 cm\(^{-1}\) and a superconducting amplitude mode, then by the BF-theory the amplitude mode should be pushed down, possibly to 6 cm\(^{-1}\), with a transfer of Raman intensity from the phonon mode to the superconducting amplitude mode. In fact, in the ratio of the Raman scattering intensities below and above Tc (see Fig. 4) an increase in scattering intensity is seen at low frequencies (below 20 cm\(^{-1}\)) at temperatures below Tc. Unfortunately, at these very low energies (6 cm\(^{-1}\)) the Raman scattering is overshadowed by strong Rayleigh-scattering, so that the 6 cm\(^{-1}\) mode cannot be observed at present in a Raman experiment.
Effects of this type were investigated intensively in YBaCuO. There a zero bias anomaly was observed as well, but the phonon Raman lines shift only by as much as 1.5% in the superconducting state [17-20]. These shifts are much smaller than expected from BF-theory. This small effect is accounted for theoretically by Zeyher and Zwicknagl [37], employing the Eliashberg strong coupling theory. They find that for an Einstein spectrum with $\omega_{ph} \approx 2 \Delta$ and $\lambda = 2.9$ the expected phonon shift is 600%, obviously the first order theory does not apply to such large shifts. Since there are 5 Cu-O stretching modes coupled with each electron, the shift of each mode is 120%. Postulating sample inhomogeneities and strong elastic scattering of the electrons and in particular, strong admixture with many other phonon modes, they claim that the maximum theoretical shift is just 5%. The observed maximum shift is 1.5%. In particular, for fully symmetric modes, and $q \to 0$, the shift is small due to the large Coulomb effects.

This leaves us with the dilemma why are the effects of superconductivity on the phonon relatively strong in $\alpha_{r}$ and $\beta_{H}^{\prime}$ (BEDT-TTF)$_2$I$_3$, while they are weak in YBaCuO. At the present stage, we can only speculate that this is associated with the (approximate) Einstein spectrum found in the BEDT-TTF salts, in contrast with the many modes in YBaCuO, and with the small coherence length $\frac{\xi}{\xi} = 15$ A in YBaCuO; thus $\frac{\delta}{\xi} \approx 4$ [38]. In $\alpha_{r}$ and $\beta_{H}^{\prime}$ (BEDT-TTF)$_2$I$_3$ the coherence length is much larger ($\frac{\xi}{\xi} \approx 100-150$ A). The BF-theory cannot be expected to apply when the coherence length is of the order of a lattice constant $a$; indeed, in this case the superconducting amplitude modes extend well into the Brillouin-zone, and neutron-diffraction experiments on YBaCuO [39] indicate that phonons over half the Brillouin zone are affected by the coupling with the amplitude modes. In $\alpha_{r}$ and $\beta_{H}^{\prime}$ (BEDT-TTF)$_2$I$_3$ because of the larger coherence length, a theory in the spirit of the BF-theory (appropriately extended to strong coupling) should apply, and account for much larger effects on $q \approx 0$ phonons. This large coherence length may perhaps be due to less elastic scattering by defects, i.e. a more perfect crystal; this is in line with the calculations of Zeyher and Zwicknagel [37] also, it is possible that the symmetry of the phonon is much lower (the space group of the crystals of $\alpha_{r}$ and $\beta_{H}^{\prime}$ (BEDT-TTF)$_2$I$_3$ is P1), thus Coulomb effects do not suppress the shift for the $q \to 0$ modes, and/or the Coulomb effects in these BEDT-TTF salts may be weaker than in YBaCuO.

**Conclusions**

At the present stage, we suggest tentatively, that based on the Balseiro-Falicov-model, the superconducting amplitude mode interacts strongly with the 30-39 cm$^{-1}$ optical phonons and thus is pushed down, possibly to 6 cm$^{-1}$ (thus yielding the zero bias anomaly [ZBA]). In this way the origin of the (as yet unaccounted for) ZBA observed in tunneling experiments can be understood. Also, it is possible that part of the amplitude of this mode is shifted up, enhancing the McMillan-Rowell peak, and thus accounting for the abnormally strong intensity of this structure. More detailed measurements, down to frequencies of ~6 cm$^{-1}$ and below, as well as temperature and magnetic field dependences are obviously needed to test this conjecture.

The strong effects observed in $\alpha_{r}$ and $\beta_{H}^{\prime}$ (BEDT-TTF)$_2$I$_3$ contrast with much weaker effects observed in YBaCuO. We are not yet able to account definitively for this difference.
